While crop production is the main agricultural activity contributing to global water pollution through the release of nutrients, pesticides, salts and sediments, livestock is the principal source of pollution by organic matter, pathogens, and emerging pollutants such as hormones and antibiotics.

Given the growing trends in livestock production (see Chapter 2), the current and predicted importance of pollutants such as zoonotic water-borne pathogens or organic matter, is probably out of the question. Nevertheless, in recent years, there have been growing concerns about new and emerging pollutants found in the aquatic environment. Such pollutants present a new water quality challenge in both developing and developed countries, due to their potential impacts on human and environmental health and the lack of regulations to monitor and control them.

This chapter provides a very brief analysis of the main agricultural sources of these pollutants and their main effects on water quality.

8.1 Organic matter

The main sources of agricultural water pollution by organic matter include livestock-related wastes such as animal excreta, uneaten animal feed, effluents from animal-processing industries and mismanaged crop residues.
Pollution by organic matter is typically measured by biological oxygen demand (BOD): the amount of oxygen used by microorganisms to decompose waste. Livestock-related wastes have the highest BOD levels (see Table 8.1). For example, the BOD of pig slurry is in the range of 30 000–80 000 milligrams per litre, as compared with the typical BOD of domestic sewage at 200–500 milligrams per litre (FAO, 2006).

As is the case for other pollutants, pollution by organic matter is growing because of increasing municipal and industrial wastewater discharge, the intensification of agriculture (including livestock farming) and reduction in river dilution capacity due to climate change and water extractions. Water pollution by organic matter from intensive livestock farming is now significantly more widespread than organic pollution from urban areas, affecting a larger extent of water bodies (Wen et al., 2017). Global meat consumption nearly doubled between 1980 and 2004, with an annual increase of around 3.6% per year; it is expected to double again by 2030 (FAO, 2011). As a result of expected urbanization, further expansion and intensification of the livestock sector (see Chapter 2), and changes in river discharge, more rivers are predicted to be degraded by organic matter beyond acceptable limits. Figure 8.1 shows that by 2050 the world’s worst water quality deterioration is projected to occur in India, sub-Saharan Africa and Mexico, with other smaller regions also facing substantial challenges. Pollution in China was the highest and most widespread in 2000 and will remain among the highest in 2050. The intensification of livestock farming is a key driver of water pollution in India, Africa and South America. By contrast, intensive livestock farming in Europe and China is expected

to stay constant or decline in the coming decades, which may reduce the pressure on very stressed river basins in these regions (Wen et al., 2017).

Locally, aquaculture can be also a major contributor to organic loads in water. In Scotland, for example, the discharge of untreated organic waste from salmon production is equivalent to 75 percent of the pollution discharged by the human population. Shrimp aquaculture in Bangladesh generates 600 tonnes of waste per day (SACEP, 2014).

Organic matter consumes dissolved oxygen in water as it degrades, contributing strongly to hypoxia in water bodies (Malling et al., 2006). The discharge of organic matter also increases the risk of eutrophication and algal blooms in lakes, reservoirs and coastal areas. The number of people thought to be potentially affected by organic pollution (BOD >5 mg/l) is projected to increase from 1.1 billion in 2000 to 2.5 billion in 2050, with developing countries disproportionately affected (Wen et al., 2017). See Figure 8.1.

![Figure 8.1](image-url)

8.2 Pathogens

Livestock excreta contain many zoonotic microorganisms and multicellular parasites, which can be harmful to human health. Pathogenic microorganisms can be water-borne or food-borne (the latter especially if the food has been irrigated with contaminated water or with untreated or partially-treated wastewater). Some pathogens can survive for days or weeks in animal faeces that have been discharged onto land and they may later contaminate water resources via runoff (FAO 2006; WHO 2012).

Pathogens from livestock that are detrimental to public health include bacteria such as *Campylobacter* spp., *Escherichia coli* O157:H7, *Salmonella* spp., *Clostridium botulinum* and parasitic protozoa such as *Giardia lamblia*, *Cryptosporidium parvum* and *Microsporidia* spp., all of which cause hundreds of thousands of infections every year (Christou, 2011).

Domestic animals, such as poultry, cattle, sheep and pigs, generate 85% of the world’s animals faecal waste, proportionally a far greater amount than is contributed by the world’s human population. The faecal production rate and contribution to the environment by these animals can be as high as $2.62 \times 10^{13}$ kg/year (WHO 2012).

Understanding and quantifying the loads, transport and fate of pathogens are challenging tasks because the environmental pathways are complex and observational data is very scarce (Atwill et al., 2012, Ferguson and Kay, 2012). The risks associated with animal waste are episodic in nature, because of sporadic loads or transmissions (e.g. after rainy events). Further complexity is added by the extreme spatial and temporal variability of weather patterns and livestock management practices in different regions of the world. Therefore, the analysis of loads and environmental pathways, particularly at scales larger than local, are typically based on models.

Cryptosporidium has been proposed as a good indicator for modelling at the global scale as it is a widespread water-borne livestock pathogen that has relatively high incidence in child diarrhoea (Liu et al., 2015). Vermeulen et al., (2017) modelled the global loads of livestock Cryptosporidium, which they estimated to be $3.2 \times 10^{23}$ oocysts per year. The study showed that cattle, especially calves, are the largest contributors to oocyst loads, followed by chickens and pigs. Spatial differences (see Figure 8.2) are linked to animal distributions. North America, Europe and Oceania together account for nearly a quarter of the total oocyst load, meaning that the developing country regions account for the largest share.

The human risks associated with pathogen pollution of water from livestock have not yet been well defined (WHO, 2012) but they are potentially high, given the number of
outbreaks of infections with zoonotic pathogens that have been reported and documented among swimmers and other water users (Dufour et al., 2012, McBride et al., 2012). For example, in one outbreak in Swaziland, cattle manure was thought to have caused more than 40 000 cases of water-borne infections (Effler et al., 2001). A more recent example is the 2016 outbreak of gastroenteritis on the North Island of New Zealand, which was attributed to the ingestion of water polluted by livestock faeces. Thousands of people were infected (Reiff, 2016).

Agricultural irrigation with untreated or partially-treated wastewater may result in the pollution by human pathogens, particularly in shallow groundwater aquifers. In the majority of low income countries, where most domestic and municipal wastewater goes untreated, alternative approaches are necessary to prevent pathogens from entering agricultural food production chains through wastewater irrigation. The WHO guidelines for the safe use of wastewater, excreta and greywater in agriculture (WHO, 2006) and the wastewater quality guidelines for agricultural use developed by FAO (1985; 1992) provide regulatory recommendations on the suitability of water for irrigation and identify possible restrictions in use.

### 8.3 Emerging pollutants

Emerging pollutants comprise a wide range of chemicals, substances and microbial pollutants that enter water bodies from various sources, including municipal wastewater treatment plants, agricultural runoff and industrial effluents. Emerging pollutants are also collectively referred to as ‘emerging contaminants’ or ‘contaminants of emerging concern’.
Emerging pollutants are broadly grouped into pharmaceuticals, personal care products, pesticides, and industrial and household chemicals. Diverse types are present in highly variable concentrations in freshwater resources such as rivers, streams lakes and groundwater. Currently, more than 700 emerging pollutants, their metabolites and transformation products, are listed as being present in the European aquatic environment (NORMAN, 2016). Nevertheless, they are rarely controlled or monitored and further research is needed to assess their impacts on human health and the environment (UNESCO, 2015b). The potential human health risks of emerging pollutants through exposure to drinking water or agricultural products is a concern (UNESCO, 2011).

Pharmaceuticals are one of the largest groups of emerging pollutants detected in water bodies. For the most part, they are excreted by humans and animals, reaching the water through the means described above. A recent study by UNESCO and HELCOM (UNESCO, 2017) found the presence of 58 different pharmaceuticals (out of 111 monitored) in rivers in the Baltic Sea region. The study reported average concentrations of less than 0.1 μg/l for top 20 pharmaceuticals in river water samples; the highest concentrations exceeded 1.0 μg/l for twelve compounds (UNESCO, 2017). The World Health Organization also has reported the presence of pharmaceuticals used for human and veterinary therapeutic and diagnostic purposes at trace levels in the range of nanograms to low micrograms per litre in surface and groundwater resources (typically less than 0.1 μg/l or 100 ng/l) (WHO, 2011).

Many emerging pollutants are known to interfere with hormone biosynthesis and metabolism in humans and animals and therefore are commonly referred to as ‘endocrine-disrupting compounds’ (EDCs) (Diamanti-Kandarakis et al., 2009). Endocrine-disrupting compounds include natural and synthetic hormones (such as estrogen), pharmaceuticals with hormonal side effects (ibuprofen, diclofenac, etc.), organochlorinated pesticides and industrial chemicals, plastics and plasticizers, fuels, and many other chemicals that are widely used in household or personal care products.

As noted above, emerging pollutants are released into the aquatic environment from a wide range of sources. Agriculture is a major source of some types of emerging pollutants. The main classes of emerging pollutants arising from agriculture and their potential routes of agricultural releases into surface waters are summarized in Table 8.1 (Boxall, 2012). These pollutants contaminate soil, groundwater and surface water through leaching and/or runoff from agricultural fields and livestock breeding facilities.

A dominant source of emerging pollutants released from agriculture into water arises from the veterinary use of medicines and hormones in aquaculture and veterinary
practices. The overuse of veterinary medicines, such as antibiotics and artificial growth hormones in industrial farming, results in the release of their residues into soil, groundwater and surface waters through leakage from animal waste storage and disposal tanks and the use of animal manure as a fertilizer. Furthermore, the excessive use of antibiotics in agriculture, farming and aquaculture contributes to the development of antimicrobial-resistant bacteria and the presence of these bacteria in water bodies (see Box 8.1). For example, some studies suggest that manure from antibiotic-treated pigs enhances the spread of antibiotic resistance in soil bacterial communities (Heuer and Schmalla, 2007), whereas filtered water from agricultural drains reduced the abundance of aquatic resistant bacteria in a shallow coastal lake (Schallenberg and Armstrong, 2004). The UNESCO and HELCOM study cited above (UNESCO, 2017) also pointed out the lack of data on the sale and consumption of veterinary pharmaceuticals, and their sources, pathways and loading onto soils, surface and groundwater systems and the

**BOX 8.1 Antimicrobial resistant microorganisms and the role of agriculture**

Large amounts of antibacterial compounds (ACs) are used across the globe to treat animals. These substances and antibacterial-resistant microbes can be released to the environment during the manufacturing process as well as through the release of animal excreta and the disposal of medical waste. Consequently, a wide range of antibacterial compounds has been detected in surface waters, groundwaters, soils and sediments in different geographical regions (Monteiro and Boxall, 2010) and elevated levels of antibacterial-resistant bacteria and markers for these have been detected in soils and surface waters impacted by human activities.

There is growing evidence that the presence of antibacterial compounds and antibacterial resistant genes (ARGs) in the natural environment indirectly affects human health and contributes to the global antibacterial resistance problem (Wellington *et al.*, 2013), which is predicted to result in millions of deaths by 2050. Once in the environment, these contaminants may persist or dissipate and will be distributed around the different environmental compartments: air, water, sediment, and biota. ACs and other chemical pollutants may also select for resistance in the environment. Humans can then be exposed to the ACs and ARGs through the breathing of dust; consumption of contaminated drinking water, plants, meat, fish and shellfish; recreational and bathing activities; and contact with wildlife. The level of exposure will be driven by a range of socio-economic, health and environmental drivers.

There is an urgent need to manage the loads and the environmental exposure to these contaminants within the agricultural sector and international organizations are already taking action to address this emerging and potentially critical issue (FAO, 2016).
aquatic environment (including agriculture and aquaculture). The study stressed the need to fill this data gap and noted that even the very scarce data available on the sale and consumption of veterinary pharmaceuticals indicate that the annual turnover can be comparable to the amount used in human medicine. Given the extent and continued growth of the livestock sector, and taking into account that animal manure is commonly applied onto the agricultural lands as fertilizer, agriculture could be a significant pathway for medical compounds to reach the aquatic environment in all regions of the world.

Agriculture may become one of the predominant sources of nanomaterials in the aquatic environment, with the use of engineered nanopesticides and nanomedicine in agriculture in the future.

Agriculture is not only a source of emerging pollutants, it also contributes to the spread and introduction of these pollutants into aquatic environments through wastewater (re)use for irrigation and the application of municipal biosolids onto the land as fertilizers (Bolong et al., 2009; Munoz et al., 2009).

An estimated 35.9 million hectares of agricultural lands are subjected to the indirect use of wastewater (Thebo et al., 2017). The potential long-term effects of emerging pollutants on human health and ecosystems as a result of wastewater use are not yet known (UNESCO, 2015b). The occurrence of a wide range of emerging pollutants in wastewater used for irrigation presents not only potentially-serious risks to human health and food safety through contaminated crops, but also spreads these pollutants to the aquatic environment and soil.

A UNESCO (2018) case study in the Oued Souhil area in Nabeul, Tunisia, indicated the occurrence of emerging contaminants in irrigation water – both in wastewater used for irrigation and in groundwater – as well as in soil. As the use of raw, insufficiently

Source: adapted from Boxall, 2012.
treated or reclaimed wastewater in agricultural irrigation continues to grow, concerns about emerging pollutants is highly significant since most of these pollutants are not adequately removed during conventional wastewater treatment. Advanced wastewater treatment technologies, (membrane/nano/ultra-filtrations, and reverse osmosis) partially remove some chemicals and pharmaceutically active compounds (Gonzalez et al., 2016). For example, the removal rate of pharmaceuticals during wastewater treatment in secondary and tertiary wastewater treatment plants in the Baltic Sea region were reported at lower than 50% for nearly half of the 118 compounds monitored; only nine were removed with an efficiency higher than 95% (UNESCO, 2017).

The use of biosolids may also lead to the contamination of human food crops and animal feed through the soil as a mediating compartment (Carballa et al., 2007). Pollutants known as endocrine disrupting chemicals (EDCs) have been found to be present in wastewater sludge (Barnabé et al., 2009).

The effects and risks of individual pollutants on aquatic organisms have been studied to a certain extent, whereas potential effects on human health have been evaluated only marginally. Cumulative effects of a mixture of different types of pollutants on human health and ecosystems have not been studied at all (UNESCO, 2011). Several research suggest that endocrine disruptors affect fertility and reproductive health and cause birth defects and developmental disorders, whereas other pollutants may cause cancerous tumours and the development of bacterial pathogen resistance (including multi-persistence) in humans and animals even at low concentrations (Poongothai et al., 2007).

The current scientific understanding on the fate and transport of emerging pollutants and their accumulation in the environment is sadly limited. They behaviour of these pollutants will differ depending on the compartment in which they are found in the environment (e.g., groundwater, surface water and sediment), due to different transformations that may take place, such as the production of by-products (metabolites and transformation products) with different ecotoxicological effects. The by-products of some pollutants are often more persistent than their parent compounds, exhibit greater toxicity and can mimic estrogenic properties (La Farré et al., 2009). Research is needed to improve our understanding of the dynamics of these pollutants in water resources and the environment, and the methods needed to remove them from wastewater (UNESCO, 2015b). More research is also needed to assess the human health and environmental risks and effects of long-term exposure to emerging pollutants, as well as to evaluate their behaviour and accumulation in ecosystems.
There are also huge gaps in the existing regulatory and monitoring frameworks, as well as in data availability regarding the occurrence of emerging pollutants in wastewater and receiving water bodies (UNESCO, 2015b). Efforts to monitor, regulate and control emerging pollutants in water resources and wastewater is limited in both developed and developing countries (UNESCO, 2015a). Data on the presence of emerging water pollutants are very scarce (UNESCO, 2011). Regulations specifically addressing these pollutants are lacking at national and international levels. Emerging pollutants are not only a major challenge facing developing countries, where water quality and pollution control is poor due to inadequate regulatory frameworks and technical and human capacities. It is also a concern in developed countries – even if a country has achieved put in place effective agricultural pollution control measures – because most emerging pollutants are currently not regulated, routinely monitored and controlled.
