#### Abstract

Sorghum and pearl millet are the staple cereals and important source of fodder for animals in the semi-arid and arid parts of India. In the present study, we have: a) characterized the distribution of sorghum and pearl millet in different production zones in India; b) estimated their rainfed potential, achievable and current levels of farmers' yields; c) quantified the gaps between farmers' yields and rainfed potential yields; and d) suggested ways to abridge the yield gaps.

Using CERES-sorghum and CERES-pearl millet crop growth models and historical weather data, rainfed potential yields and water balance of sorghum (kharif and rabi) and pearl millet were estimated for selected locations in different production zones. Simulated yields were supplemented with the research station yields of rainfed trials and yields of frontline demonstrations, both obtained from the reports of the All India Coordinated Crop Improvement Projects on Sorghum and Pearl Millet. District level yields were considered as farmers' yields. Based on these data, the yield gaps at various management levels were estimated.

The farmers' average yield was $970 \mathrm{~kg} \mathrm{ha}^{-1}$ for kharif sorghum, $590 \mathrm{~kg} \mathrm{ha}^{-1}$ for rabi sorghum and 990 kg ha ${ }^{-1}$ for pearl millet. Simulated rainfed potential yield in different production zones ranged from 3210 to $3410 \mathrm{~kg} \mathrm{ha}^{-1}$ for kharif sorghum, 1000 to $1360 \mathrm{~kg} \mathrm{ha}^{-1}$ for rabi sorghum and 1430 to $2090 \mathrm{~kg} \mathrm{ha}^{-1}$ for pearl millet. Total yield gap (simulated rainfed potential yield - farmers' yield) in production zones ranged from 2130 to $2560 \mathrm{~kg} \mathrm{ha}^{-1}$ for kharif sorghum, 280 to $830 \mathrm{~kg} \mathrm{ha}^{-1}$ for rabi sorghum and 680 to $1040 \mathrm{~kg} \mathrm{ha}^{-1}$ for pearl millet. This indicates that productivity of kharif sorghum can be increased 3.0 to 4.0 times, rabi sorghum 1.4 to 2.7 times and pearl millet 1.8 to 2.3 times from their current levels of productivity.

To abridge the yield gaps of sorghum and pearl millet, integrated watershed-based approach encompassing harvesting of excess rainfall for supplemental irrigation, growing high yielding crop cultivars, integrated nutrient management and integrated pest and disease management would be required. Value addition of products and their multiple uses are necessary to make them more remunerative for the farmers.

This publication is part of the research project "Comprehensive Assessment of Water Scarcity and Food Security in Tropical Rainfed Water Scarcity System: A Multi-level Assessment of Existing Conditions, Response Options and Future Potentials" funded by the Government of Netherlands and ICRISAT.

## Executive Summary

Sorghum (Sorghum bicolor (L.) Moench) and pearl millet (Pennisetum glaucum (L.) R.Br) are the staple cereals grown in the semi-arid and arid parts of India. They are also an important source of fodder for animals. While sorghum is grown both in the rainy (kharif) and postrainy (rabi) seasons, pearl millet is a completely rainy season crop, grown in hot and arid climate on marginal and least fertile soils where no other crop can survive.

With the increase in human and animal population and a fragile balance between food supplies and its demand, production of sorghum and pearl millet must be increased to meet the current and future food and fodder needs. The present study estimated the production potential, yield gap and water balance of various production zones under sorghum and pearl millet cultivation to assess the scope for enhancing their production in India.

Based on the share of cultivated area in a district to the total cropped area in the country, the districts were ranked for each crop. The top districts covering $50 \%$ of the cropped area were grouped into primary production zone. Similarly, next group of districts covering $35 \%$ ( $50 \%$ to $85 \%$ ) of the total cropped area were placed in the secondary production zone. The districts which had $<1000$ ha sown to the crop were grouped as "others" and the rest were placed in the category of tertiary production zone. Similarly, the production and productivity were also studied in different states and AEZs.

CERES-sorghum and CERES-pearl millet models available in DSSAT v3.5 were used to simulate the growth and yield of sorghum and pearl millet, respectively, to quantify their potential productivity at selected locations in India. These estimates of potential yields, along with the experiment station, frontline demonstration (FLD) and district level yields, were used to assess yield gaps at various levels of technology adoption. Total yield gap (YG) was defined as the yield gap between simulated long-term mean yield and the district level mean yield. Total yield gap was further divided into yield gap I (YG I) and yield gap II (YG II). YG I is the gap between simulated long-term mean yield and the on-farm (FLD) mean yield. YG II is the gap between FLD mean yield and district level mean yield.

Kharif sorghum is currently grown on 4.56 million hectares ( M ha ) with a production of 4.40 million tons ( M t) and an average productivity of $970 \mathrm{~kg} \mathrm{ha}^{-1}$. Maharashtra, Madhya Pradesh and Karnataka are the major kharif sorghum producing states. For the primary production zone, the simulated rainfed potential, frontline demonstration (FLD) and district mean yields were 3210, 1810 and $1080 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. For the secondary zone, the yields in the same order were 3390,1880 and $860 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively; and for the tertiary zone, these were 3410,1840 and $850 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Total yield gaps for the primary, secondary and tertiary zones were 2130,2530 and $2560 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. The lowest yield gap in the primary production is mainly due to the low and erratic rainfall. While YG I was 60 to $65 \%$, YG II was 35 to $40 \%$ of the total yield gap. Mean seasonal rainfall was 660 mm for the primary zone, 770 mm for the secondary zone and 660 mm for the tertiary zone, respectively. It was estimated that out of 660 to 770 mm of seasonal rainfall in the production zones, about $50 \%$ was lost as surface runoff and deep drainage.

Mid-season drought is the major constraint for kharif sorghum across the production zones in India. Apart from that, pests like shoot fly, stem borer and head bug cause damage to the crop. Diseases like grain mold, followed by ergot are the major yield reducers. Farmer's preference for pearly white grain
and roundness of the grain are the other constraints for the adoption of improved varieties and hybrids of sorghum. These grain qualities are consumer preferred and often dictate market prices for the produce.

Rabi sorghum is grown on 5.11 M ha with a total production of 2.99 Mt and an average productivity of $590 \mathrm{~kg} \mathrm{ha}^{-1}$. It is grown mostly in Maharashtra and Karnataka and in some parts of Andhra Pradesh. Simulated rainfed potential, FLD and district mean yields of rabi sorghum were 1310, 1480 and 480 kg $\mathrm{ha}^{-1}$, respectively, for the primary zone. For the secondary zone, the yields in the same order were 1360, 1290 and $680 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. For the tertiary zone, simulated rainfed potential and district mean yields were 1000 and $750 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively and the FLD yields were not available. Primary production zone had the highest gap of $830 \mathrm{~kg} \mathrm{ha}^{-1}$, followed by secondary production zone with a gap of $680 \mathrm{~kg} \mathrm{ha}^{-1}$ and tertiary zone with a gap of $280 \mathrm{~kg} \mathrm{ha}^{-1}$. Yield gaps I and II for the production zones could not be estimated accurately because of insufficient FLD data.

Mean rainfall during rabi season varied from 60 mm for the tertiary zone to 180 mm for the primary zone, with a high coefficient of variation ranging from $43 \%$ to $94 \%$ across locations within each production zone. Water surplus (runoff plus deep drainage) was negligible ranging from 20 to 90 mm in the production zones. Terminal drought is the major abiotic constraint for rabi sorghum. Shoot fly, head bugs and stalk rot are the major biotic constraints for rabi sorghum.

Pearl millet is grown on 9.4 M ha producing 8.5 Mt with an average productivity of $990 \mathrm{~kg} \mathrm{ha}^{-1}$. Most of the area under pearl millet is in Rajasthan, Gujarat and Maharashtra. For the primary production zone, the simulated rainfed potential, frontline demonstration (FLD) and district mean yields were 1430, 1810 and $750 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. For the secondary zone, the yields in the same order were 1960, 1600 and $1060 \mathrm{~kg} \mathrm{ha}^{-1}$; and for the tertiary zone, these were 2090, 2190 and $1050 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Mean FLD yield across the production zones was $1870 \mathrm{~kg} \mathrm{ha}^{-1}$, which is similar to the simulated rainfed mean yield. Primary production zone had the lowest yield gap of $680 \mathrm{~kg} \mathrm{ha}^{-1}$, followed by the secondary zone with a gap of $900 \mathrm{~kg} \mathrm{ha}^{-1}$ and the tertiary zone with a gap of 1040 kg ha ${ }^{-1}$. Total yield gap across all the production zones was $880 \mathrm{~kg} \mathrm{ha}^{-1}$. Yield gap II formed a larger part of the total yield gap, indicating greater scope for adopting the already available technologies by farmers for increasing production.

Mean seasonal rainfall in the primary zone was the lowest at 330 mm , followed by 420 mm in the secondary zone and 530 mm in the tertiary zone. Mean simulated water surplus (runoff plus deep drainage) was 140 mm for the primary, 180 mm for the secondary and 270 mm for the tertiary zones. Drought is the major constraint of pearl millet across all the production zones. Among the biotic constraints, downy mildew is the most widespread and destructive disease of pearl millet, causing severe economic losses. Other minor diseases affecting pearl millet are smut, ergot and rust.

The above analysis indicated that under rainfed situation the productivity of kharif sorghum could be increased 3.0 to 4.0 times, rabi sorghum 1.4 to 2.7 times and pearl millet 1.8 to 2.3 times from their current levels of productivity. Further improvements in yield are possible with the provision of supplemental irrigation. This requires integrated watershed-based approach that involves harvesting of excess rainfall for supplemental irrigation, growing high yielding crop cultivars with desirable quality traits, integrated nutrient management and integrated pest and disease management. Value addition of products and their multiple uses are necessary to make them more remunerative for the farmers.

## 1. Background

Sorghum (Sorghum bicolor (L.) Moench) and pearl millet (Pennisetum glaucum (L.) R.Br) are the rainfed cereals grown in the semi-arid and arid parts of India. Apart from serving as staple cereal for the poor in India, they are also an important source of fodder for domestic animals. While sorghum is grown both in the rainy (kharif) and postrainy (rabi) seasons, pearl millet is rainy season crop, grown in relatively warmer climate than sorghum.

After mid-eighties, the production of sorghum declined sharply. This was due to a steep decline in the total cultivated area as a result of changes in government policies and expanding irrigation facilities that favored cultivation of other high value crops and changes in food habits of people. Currently, kharif and rabi sorghum are grown on about 9.67 million hectare (M ha) in India (Database: 200002). Maharashtra accounts for the largest production, followed by Karnataka, Andhra Pradesh and Madhya Pradesh. Despite decline in total production in recent years, the overall productivity of the sorghum has increased from $470 \mathrm{~kg} \mathrm{ha}^{-1}$ in 1970 to $880 \mathrm{~kg} \mathrm{ha}^{-1}$ in 2005. There is a huge demand for rabi sorghum for grain and fodder, especially during lean months in Maharashtra and the neighboring states. Rather than high yielding varieties, good irrigational facilities contributed to the rise in productivity of rabi sorghum.
Pearl millet is the most important cereal crop in the arid regions of India. It is grown on 9.4 M ha with an average productivity of $900 \mathrm{~kg} \mathrm{ha}^{-1}$ (Database: 2001-03). However, even with an increased production over the years, its productivity is still much below the potential levels. The production can be increased with improved management and high yielding cultivars.

In order to develop a suitable strategy to improve the productivity levels of sorghum and pearl millet, it is imperative to assess the potential yield and yield gaps between potential and actual yields. Many field trials are conducted every year at research stations and on-farms under the All India Coordinated Crop Improvement Projects on Sorghum and Pearl Millet. The yields reported in these trials can be used for determining production potential at various management levels. However, there are hiccups as the yields reported in these trials conducted over locations and seasons are sometimes confounded because of inadequate considerations to genotype, climatic factors and their variability and agronomic management. Alternatively, crop growth models, which integrate the effect of different factors on yield, could be used to estimate the potential productivity for large number of diverse locations. The present study investigated the potential productivity and yield gap of kharif and rabi sorghum and pearl millet for their production zones in India. Spatial and temporal variations in yield gap at various technological levels, i.e., yield gaps between simulated potential rainfed yields, experimental station rainfed yields, frontline demonstration yields and farmer's actual yields have been presented. Water balance components for the production zones of these crops were also estimated to assess constraints and opportunities for increasing their production and productivity in India.

## 2. Definitions, Data Sources and Methods

### 2.1 Delineation of Production Zones

District level databases on area, production and productivity of kharif and rabi sorghum and pearl millet crops available for 2000-2003 were used to delineate the production zones for each crop. The delineation procedure was the same for the three crops. The districts were ranked based on the share of area in a district to the total area for the crop in the country. The top districts covering $50 \%$ of the cropped area were grouped into primary production zone. The next group of districts covering $35 \%$ ( $50 \%$ to $85 \%$ ) of the total cropped area were placed in secondary production zone. The next group of districts which had $<1000$ ha sown to the crop were grouped as "others" and the rest were placed in the category of tertiary production zone.

### 2.2 Experimental Station Yield

This is the maximum possible rainfed yield (observed rainfed yield potential) using an improved cultivar. The crop is grown under controlled field conditions with improved management practices. For kharif and rabi sorghum, we reviewed the annual reports of the All India Coordinated Sorghum Improvement Project (AICSIP) and collected yield data of all the entries in rainfed trials conducted at several locations for the last ten-years. The yield data thus obtained for a given crop was averaged over all the entries in the trial for each location and year. Subsequently, these means were further averaged over the ten-year period for each location to determine the mean yield potential for a location.

For pearl millet, we reviewed the annual reports of the All India Coordinated Pearl Millet Improvement Project (AICPMIP) and collected yield data of all entries in the rainfed trials conducted from 1990 to 2002 under improved management practices at 15 locations in the country. Mean yield potential of pearl millet for a location was calculated using the similar method as for sorghum.

### 2.3 On-farm Yields with Improved Management

The crop yield data of front line demonstrations (FLD) conducted by ICAR and reported in AICSIP and AICPMIP annual reports were used. FLD trials were conducted each year at several locations in a district and a mean value for the district was calculated. The FLD data were averaged over the years to calculate the mean FLD yield for the district. FLD yields represented the achievable yields with improved management under on-farm situations.

### 2.4 District Average Yields

District yields represent farmers' yields under traditional management. District level area and production data of kharif and rabi sorghum and pearl millet were obtained from the reports published by the Bureau of Economics and Statistics of different state governments. District average yields were then calculated from the data and averaged over the years as done for experimental yields data of sorghum and pearl millet.

### 2.5 Data sets of Experimental Station, On-Farm and District Yields of Kharif and Rabi Sorghum

For kharif sorghum, the experimental station data was available from 20 locations. Seven locations belonged to the primary, six to the secondary and seven to the tertiary zone. FLD data was available for four, one and two locations falling in the primary, secondary and tertiary zones, respectively. District yield data was available for all the locations, except for one location in tertiary zone of Gujarat.

For rabi sorghum, the experimental station data was available for 11 locations. Four locations belonged to the primary, five to the secondary and two to the tertiary zone. FLD data was available for three locations in the primary zone, one location in the secondary zone and none in the tertiary zone. District yield data was available for all the locations.

### 2.6 Data sets of Experimental Station, On-Farm and District Yields of Pearl Millet

Experimental station data for pearl millet was available for 16 locations. Three locations belonged to the primary, five to the secondary and six to the tertiary zone and two to the "others" category. FLD data was available for only one location in the primary, three locations in the secondary and two locations in the tertiary zone and none in the "others" category. District yield data was available for all the locations.

### 2.7 Simulation of Kharif and Rabi Sorghum Yields

ICRISAT has extensively validated the CERES-sorghum model to evaluate yield gaps in different agroecological subregions in peninsular India (Virmani and Alagarswamy 1993). For the present study, the same version of the model available in DSSAT v3.5 (Decision Support System for AgroTechnology Transfer, Jones et al. 1998) was adopted to carryout multi-year simulations of sorghum growth and yield for each selected location in the production area. The model needs inputs of daily data of rainfall, maximum and minimum temperatures and solar radiation, cultivar-specific coefficients (genetic coefficients) and soil profile characteristics for model execution. For this purpose, long-term real weather data were collected for the kharif and rabi sorghum locations (Tables $1 \& 2$ ). When solar radiation data was not available, it was estimated from sunshine hours. Otherwise, radiation was estimated from air temperatures, according to Bristow and Campbell (1984). Soil inputs for different locations were extracted from descriptions of established soil series of India (Lal et al. 1994). This model was further tested with the crop growth and soil water dynamics data of two seasons at ICRISAT. Crop growth and yield of an improved variety under rainfed situation for a location were simulated considering nutrients and pests are not limiting the crop growth. For rainy season (kharif) sorghum, we used cv. CSV 15 and for the postrainy season (rabi) sorghum we used cv. M 35-1. The same cultivars were used for model calibration, testing and long-term simulations for different locations. The details of locations for which simulations were carried out are given in Tables 1 and 2. Long-term outputs of crop yields and water balance were used to assess the potentials and constraints to crop production for several locations across India.

### 2.8 Simulation of Pearl Millet Yields

To simulate rainfed potential yields of pearl millet, we used CERES-pearl millet model available in DSSAT v3.5 (Decision Support System for Agro-Technology Transfer, Jones et al. 1998). The model was calibrated and validated with two seasons of crop growth and soil water dynamics data from ICRISAT. For pearl millet, we used cultivar ICTP 8203. The same cultivar was used for model calibration, testing and long-term simulations for different locations. The details of locations and the number of years for which simulation runs were carried out are given in Table 3. Other model inputs and treatment of data for model simulation were the same as for the CERES-sorghum model.

Table 3. Geographic details of locations, soil series and number of years for which simulations were carried out for pearl millet.

| Location | State | Soil series | AWHC* (mm) | No. of years | Latitude $\left({ }^{\circ} \mathrm{N}\right)$ | Longitude <br> $\left({ }^{\circ} \mathrm{E}\right)$ | AEZ ${ }^{+}$ |

### 2.9 Quantification of Yield Gaps

Yield gaps were estimated using simulated yields, experimental station yields, FLD yields and district average yields. Two types of yield gaps estimated were yield gap I and yield gap II. Yield gap I is the yield gap between the experimental station yield and the yield of the front line demonstrations (FLD). Yield gap II is the yield gap between FLD yield and the district average yield. Difference between the experimental station yield and the farmers' average yield is the total yield gap. The yield gaps were also calculated as the difference between simulated rainfed yields and the district average yields.

## 3. Production Trends of Sorghum in the World and India

### 3.1 Sorghum Production in the World

Globally, about 49 M ha of sorghum was cultivated in 1970. Since then, over the 36 years period, its area has declined to 44.7 M ha in 2005 (Fig. 1). World productivity of sorghum hovered around 1 t ha ${ }^{-1}$ during early seventies and gradually increased to $1.4 \mathrm{t} \mathrm{ha}^{-1}$ towards early eighties. Productivity of sorghum was $1.3 \mathrm{t} \mathrm{ha}^{-1}$ in 2005. About 19 per cent of the sorghum area is in India. India, Nigeria and Sudan put together have more than 50 per cent of global area under sorghum (Table 4). However, in terms of productivity, Nigeria is at $48^{\text {th }}$ position with a productivity of $1260 \mathrm{~kg} \mathrm{ha}{ }^{-1}$, India is at $67^{\text {th }}$ position with a productivity of $880 \mathrm{~kg} \mathrm{ha}^{-1}$ and Sudan is at $73^{\text {rd }}$ position with a productivity of 660 kg ha ${ }^{-1}$. It is clear that the countries with large areas under sorghum cultivation have very low productivity (Table 4).

### 3.2 Sorghum Production in India

In India, sorghum area has declined from 17 M ha in 1970 to about 8.7 M ha in 2005. However, sharp decline in area occurred after mid-eighties (Table 4 and Fig. 2). In spite of year-to-year variation in total production, the production of sorghum increased until mid-eighties primarily due to yield increase. After mid-eighties, the production declined sharply due to decline in area because of competition by other crops. Maharashtra is the largest state with 52.7 per cent of total sorghum area and contributing 54.8 per cent of the total production of sorghum in India. Karnataka, Andhra Pradesh and Madhya Pradesh are the other three major sorghum producing states with 30.9 per cent to total sorghum area and 34.1 per cent to total production. In spite of decline in total production in recent years, the productivity of the crop increased from $470 \mathrm{~kg} \mathrm{ha}^{-1}$ in 1970 to $880 \mathrm{~kg} \mathrm{ha}^{-1}$ in 2005.

Figure 2. Area, production and productivity of sorghum in India (Source: FAOSTAT, 2006).

### 4.0 Yield Gap Analysis of Kharif Sorghum

### 4.1 Abstract

Kharif sorghum is an important staple food for poor people and source of feed and fodder for livestock production in India. Considering its importance in the near future as a source of food for people, feed and fodder for animals for draft and milk production and also as a source of bio-energy, its production and productivity must be increased. The present study estimated the production potential and yield gap of kharif sorghum to assess the scope for increasing its production.

CERES-sorghum model available in DSSAT v3.5 was used to simulate sorghum growth and yield to quantify the potential productivity of kharif sorghum for selected locations. These estimates along with experiment station yields, frontline demonstration (FLD) yields and district level yield data were used to assess yield gaps. For the primary production zone, the simulated rainfed potential, frontline demonstration (FLD) and district mean yields were 3210, 1810 and $1080 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. For the secondary zone, the yields were 3390,1880 and $860 \mathrm{~kg} \mathrm{ha}^{-1}$; and for the tertiary zone, these were 3410 , 1840 and $850 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Total yield gaps (simulated potential minus district average yield) for the primary, secondary and tertiary zones were 2130,2530 and $2560 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Yield gap I (simulated potential minus FLD yield) was 60 to $65 \%$ and yield gap II (FLD minus average farmer yield) was 35 to $40 \%$ of the total yield gap, indicating the need to transfer available kharif sorghum production technologies from experiment station to the on-farm situations. Mid-season drought is the major yield reducer of kharif sorghum. It was estimated that out of 660 to 770 mm of seasonal rainfall in the production zones, about $50 \%$ is lost as surface runoff and deep drainage. Integrated watershed management approach, encompassing harvesting and storing of excess water for supplemental irrigation, improved cultivars, integrated nutrient and pest management practices are required to abridge the yield gaps of kharif sorghum.

### 4.2 Introduction

Traditionally, kharif sorghum has been grown in the states of Maharashtra, Gujarat, Karnataka, Andhra Pradesh and Madhya Pradesh. With the exception of Maharashtra, there has been significant reduction in area and production of kharif sorghum. Over the years, kharif sorghum growing area has been replaced variously across states by competing high value crops like groundnut, sunflower, soybean, pigeonpea, chickpea, maize, castor and cotton. Currently, Maharashtra, Karnataka, Andhra Pradesh and Madhya Pradesh are the major sorghum producing states. As per the current estimates, kharif sorghum is grown on 4.56 M ha with an average productivity of $970 \mathrm{~kg} \mathrm{ha}^{-1}$. Despite the declining trends in per capita consumption of sorghum as food, it remains as the important and easily accessible staple cereal for the economically deprived people in India.

The present study investigated the production potential and yield gap of kharif sorghum in the major sorghum growing areas of India. Spatial and temporal variations in yield gap at various technological levels, i.e., yield gaps between simulated potential rainfed yields, experimental station rainfed yields, frontline demonstration yields and farmer's actual yields are also presented. Water balance components of kharif sorghum production were also evaluated to assess constraints and opportunities for increasing its production and productivity in India.

### 4.3 Production Zones and Soil Resources of Kharif Sorghum

In India, the primary kharif sorghum production zone comprises 22 districts with about 2.26 M ha (Fig. 3). Out of these districts, 11 districts belong to Maharashtra with annual rainfall ranging from 300 to 750 mm . The remaining districts are in Rajasthan, Madhya Pradesh, Andhra Pradesh, Karnataka and Tamil Nadu. The secondary production zone covers 55 districts with 35 per cent of the total area; whereas the tertiary zone covers 137 districts with 15 per cent of the total area under kharif sorghum. The 116 districts in the category of "others" have negligible area and production of the crop.

Figure 3. Production zones of kharif sorghum in India (Database: 1995-98).

Primary production zone is dominated by Entisols, occupying about 45.6 per cent area, followed by Vertisols with $36.2 \%$ area (Table 5 and Fig. 4). Other important soils are Alfisols, Inceptisols and Aridisols. Vertisols (mainly Usterts) occupy 38 per cent of the secondary production zone. Entisols cover 27.5 per cent of the area, followed by Inceptisols, Alfisols and Aridisols. Tertiary production zone has a fairly even distribution of Entisols, Alfisols, Inceptisols and Vertisols with a little area covered by Aridisols. Thus, Vertisols and Entisols are dominant soil orders in primary and secondary zones where kharif sorghum production is concentrated. High rainfall or irrigation may be the reason for its even distribution on soil orders in the tertiary zone.

Table 5. Relative distribution of soil resources in production zones of kharif sorghum.

| Primary zone |  | Secondary zone |  | Tertiary zone |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Soil type | Area (\%) | Soil type | Area (\%) | Soil type | Area (\%) |
| Entisols | 45.6 | Vertisols | 38.0 | Entisols | 29.1 |
| Vertisols | 36.2 | Entisols | 27.5 | Alfisols | 25.7 |
| Alfisols | 9.3 | Inceptisols | 13.3 | Inceptisols | 20.7 |
| Inceptisols | 5.5 | Alfisols | 12.2 | Vertisols | 16.3 |
| Aridisols | 3.3 | Aridisols | 8.2 | Aridisols | 6.6 |

Figure 4. Soil resources in different production zones of kharif sorghum in India.

### 4.4 Kharif Sorghum Productivity in Production Zones, AEZs and States of India

Kharif sorghum productivity in production zones: Productivity of primary zone is the highest at 1080 $\mathrm{kg} \mathrm{ha}^{-1}$ with a coefficient of variation (CV) of $47 \%$ (Table 6). Secondary and tertiary zones have similar productivities (860 and $850 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively) with a CV of $51 \%$ and $47 \%$, respectively. The production zone classified as "others" has the lowest productivity of $740 \mathrm{~kg} \mathrm{ha}{ }^{-1}$ with a CV of $52 \%$. These results show that production of kharif sorghum decreases as one moves away from the primary production zone to the secondary or tertiary zone with little change in CV of yields.

${ }^{*}$ Coefficient of variation among districts.
Kharif sorghum productivity in agroecological zones: AEZ 6 is termed as semi-arid dry and moist zone. Length of growing period (LGP) varies from 60 to 180 days. This zone encompasses 31 districts, with most of them from Maharashtra and Karnataka. AEZ 6 has the maximum area ( 1.91 M ha ) and the maximum kharif sorghum production ( 2.49 Mt ) in the country, constituting $42 \%$ of the total area and $56 \%$ of total production (Table 7 and Fig. 5). Average productivity of this zone is one of the highest ( $1300 \mathrm{~kg} \mathrm{ha}^{-1}$ ).

AEZ 4 has semi-arid dry climate with LGP varying from 90 to 120 days. Available water holding capacity (AWHC) of soils in the rooting zone varies from 100 to 200 mm . Ajmer and Tonk districts of Rajasthan are in this zone. AEZ 4 ranks second in terms of area ( 0.77 M ha) and production ( 0.39 M t ) in the country. The average productivity of this zone is $500 \mathrm{~kg} \mathrm{ha}^{-1}$. This zone is followed by AEZ 5 in terms of area ( 0.42 M ha ) and production ( 0.37 M t ) of kharif sorghum. AEZ 5 has semi-arid moist climate. AWHC of soils in this zone range from 50 to 150 mm . The LGP is 90 to 150 days. East and West Nimar districts of Madhya Pradesh fall in this zone. Average productivity of this zone is 880 kg $h^{-1}$. Kharif sorghum in AEZ 8 comes under semi-arid dry and moist climate with LGP varying from 90 to 150 days. Soils have low AWHC ( 50 to 150 mm ). The total area under the crop is 0.38 M ha with a total production of 0.32 Mt and average productivity of $830 \mathrm{~kg} \mathrm{ha}{ }^{-1}$. AEZ 10 has sub-humid moist and dry climate, covering 32 districts. It has the fifth largest area ( 0.37 M ha ) and production $(0.33 \mathrm{M} \mathrm{t})$ in the country. The average productivity is $890 \mathrm{~kg} \mathrm{ha}^{-1}$. Coimbatore and Tiruchirapally districts of Tamil Nadu fall in this zone. AEZ 7 is termed as semi-arid moist zone with a growing season of 90 to 100 days. AWHC of soils range from 100 to 120 mm . Mahabubnagar, Medak and Ranga Reddy districts of Andhra Pradesh come in this zone. This zone has an average productivity of 860 kg $h^{-1}$. AEZ 2 and 3 have arid climate and LGP is about 60 days. Jodhpur and Nagaur (AEZ 2) of Rajasthan and Bellary and Bijapur districts of Karnataka (AEZ 3) fall in this agroclimate. The average productivity of AEZ 2 and AEZ 3 is $220 \mathrm{~kg} \mathrm{ha}^{-1}$ and $1420 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. The other AEZs have small area under kharif sorghum and their average productivity range from 430 to $1440 \mathrm{~kg} \mathrm{ha}^{-1}$.

Figure 5. Agroecological zones of kharif sorghum in India.

Kharif sorghum productivity in different states of India: Maharashtra is the largest kharif sorghum growing state with about 1.8 M ha out of the total 4.56 M ha grown in India. Madhya Pradesh and Rajasthan come next with 0.61 M ha each followed by Karnataka with 0.34 M ha (Table 8). Maharashtra produces 2.3 Mt out of a total production of 4.40 Mt of sorghum produced in the country. The productivity in Maharashtra is $1280 \mathrm{~kg} \mathrm{ha}^{-1}$. About 28 districts in Maharashtra grow kharif sorghum. The variability of productivity across these districts is also high with a CV of 26 per cent. Madhya Pradesh grows sorghum in 45 districts with a mean productivity of $860 \mathrm{~kg} \mathrm{ha}^{-1}$. Variability of productivity across districts in this state is high with a CV of 30 per cent. Karnataka grows kharif sorghum in 21 districts with a mean productivity of $1300 \mathrm{~kg} \mathrm{ha}^{-1}$, which is the highest in the country. Uttar Pradesh, Andhra Pradesh, Tamil Nadu and Gujarat are the other states having large area under sorghum. However, the area under sorghum in these states has declined drastically in the recent years. All other states have very little areas under sorghum.

### 4.5 Rainfed Yield Potential of Kharif Sorghum

Experimental station yields and yield gaps: Primary zone has locations from Maharashtra, Karnataka and Andhra Pradesh. Out of all the locations, Dharwad had the maximum experiment station and FLD yields. For other locations, the experiment station yields ranged from 3230 to $3810 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 9). For the primary zone, the mean experiment station yield was $3770 \mathrm{~kg} \mathrm{ha}^{-1}$, the mean FLD yield was $1810 \mathrm{~kg} \mathrm{ha}^{-1}$ and the mean district yield was $1330 \mathrm{~kg} \mathrm{ha}^{-1}$. The yield gaps I and II for this zone were 2120 and $630 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Based on the mean experiment station and the mean district yields, the total yield gap was $2440 \mathrm{~kg} \mathrm{ha}^{-1}$. For the secondary zone, the experiment station yields ranged from 2240 to $4080 \mathrm{~kg} \mathrm{ha}^{-1}$ across locations. FLD yield was available only for Surat in Gujarat, which was $1880 \mathrm{~kg} \mathrm{ha}^{-1}$. For this zone, mean experimental station yield was $3440 \mathrm{~kg} \mathrm{ha}^{-1}$ and the corresponding mean district yield was $1250 \mathrm{~kg} \mathrm{ha}^{-1}$. Mean yield gaps I and II were 2010 and $680 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Total yield gap for the secondary zone on average was $2190 \mathrm{~kg} \mathrm{ha}^{-1}$. Mean experimental station yields for the tertiary zone ranged from 2280 to $3960 \mathrm{~kg} \mathrm{ha}^{-1}$ across locations. FLD yields were available for only two locations. For this zone, mean experimental yield was $3250 \mathrm{~kg} \mathrm{ha}^{-1}$, mean FLD yield was $1840 \mathrm{~kg} \mathrm{ha}^{-1}$ and the district average yield was $1050 \mathrm{~kg} \mathrm{ha}^{-1}$. Yield gaps I and II for this zone were 1430 $\mathrm{kg} \mathrm{ha}^{-1}$ and $1050 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Thus, the total yield gap was $2260 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 9). These results
indicate that substantial total yield gap ( 2190 to $2440 \mathrm{~kg} \mathrm{ha}^{-1}$ ) for kharif sorghum exists for the production zones. Yield gap I was larger than yield gap II for the production zones, indicating the need to transfer and adopt technologies from on-station to on-farm to benefit farmers.

### 4.6 Simulated Potential Rainfed Yields

Potential yield of locations: In the primary zone, the mean yield across locations ranged from 2510 kg $\mathrm{ha}^{-1}$ to $3670 \mathrm{~kg} \mathrm{ha}^{-1}$ with a mean yield of $3210 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 10). The coefficient of variation ranged from $9 \%$ to $30 \%$, primarily due to variability in rainfall at these locations. Maximum possible yield under rainfed situation ranged from $3770 \mathrm{~kg} \mathrm{ha}^{-1}$ to $5250 \mathrm{~kg} \mathrm{ha}^{-1}$ and the minimum yields from 580 kg $\mathrm{ha}^{-1}$ to $3240 \mathrm{~kg} \mathrm{ha}{ }^{-1}$. For the secondary production zone, the mean yield across locations ranged from $1570 \mathrm{~kg} \mathrm{ha}^{-1}$ (Jodhpur) to $4430 \mathrm{~kg} \mathrm{ha}^{-1}$ (Dhar) with an overall mean of $3390 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 10).

Rajasthan had the highest coefficient of variation (CV) in yield with $46 \%$ for Jodhpur and $53 \%$ for Kota, respectively. The locations with low CV were Belgaum (17\%) and Betul (14\%), which is due to high rainfall at these locations. Maximum yields ranged from $2830 \mathrm{~kg} \mathrm{ha}^{-1}$ to $5340 \mathrm{~kg} \mathrm{ha}^{-1}$; whereas the minimum yields ranged from nil to $3110 \mathrm{~kg} \mathrm{ha}^{-1}$ across locations. For the tertiary zone, the mean yields across locations ranged from $2520 \mathrm{~kg} \mathrm{ha}^{-1}$ to $4380 \mathrm{~kg} \mathrm{ha}^{-1}$ with a mean yield of $3410 \mathrm{~kg} \mathrm{ha}{ }^{-1}$. Maximum yields across locations ranged from 3750 to $4870 \mathrm{~kg} \mathrm{ha}^{-1}$; whereas the minimum yields ranged from 0 to $2680 \mathrm{~kg} \mathrm{ha}^{-1}$. The CV ranged from 11 to $50 \%$. Complete crop failure (nil simulated yield) occurred in the years with a long spell of drought after germination.

Potential yield of production zones: Primary production zone had the lowest mean rainfed yield potential with $3210 \mathrm{~kg} \mathrm{ha}^{-1}$, while the tertiary zone had $3410 \mathrm{~kg} \mathrm{ha}^{-1}$. Because of high mean rainfall, the range and CV in mean yield were the highest in the secondary zone; whereas these were low for the primary and tertiary zones because of better distribution of crop season rainfall. Within the production zones, the mean yield of locations ranged from 2510 to $3670 \mathrm{~kg} \mathrm{ha}^{-1}$ for the primary zone; 1570 to 4430 $\mathrm{kg} \mathrm{ha}{ }^{-1}$ for the secondary zone; and 2520 to $4380 \mathrm{~kg} \mathrm{ha}^{-1}$ for the tertiary zone.

Potential yield of major states: Simulated rainfed sorghum yields in Karnataka, Maharashtra and Madhya Pradesh were more than $3 \mathrm{t} \mathrm{ha}{ }^{-1}$ (Table 11). Maharashtra had the lowest mean simulated yield of 3220 kg ha ${ }^{-1}$. The mean rainfed potential yield in Karnataka and Madhya Pradesh were 3640 and $3610 \mathrm{~kg} \mathrm{ha}{ }^{-1}$, respectively. Mean crop season rainfall was the maximum ( 890 mm ) in Madhya Pradesh. Karnataka had a mean crop season rainfall of 650 mm , with high CV of $40 \%$ across the locations. High rainfed potential yields were associated with the high amount of seasonal rainfall in a state.

Potential yield of agroecological zones: AEZ 6 had the lowest crop season mean rainfall of 600 mm with a CV of 26 per cent across locations (Table 11). The lowest long-term mean yield of 3270 kg $\mathrm{ha}^{-1}$ was simulated for the AEZ 6. AEZ 5 had a mean yield of $3480 \mathrm{~kg} \mathrm{ha}^{-1}$ with a high CV of 20 per cent across locations. AEZ 10 had the highest mean simulated yield of $3550 \mathrm{~kg} \mathrm{ha}^{-1}$. This zone also had the highest mean rainfall of 900 mm .

Table 11. Rainfed simulated potential yields ( $\mathrm{kg} \mathrm{ha}^{-1}$ ) of kharif sorghum and seasonal rainfall (mm) in different crop production zones, states and AEZs.

### 4.7 Yield gaps

Yield gap of production zones: Simulated mean yields varied from $3210 \mathrm{~kg} \mathrm{ha}^{-1}$ to $3410 \mathrm{~kg} \mathrm{ha}^{-1}$, progressively increasing from primary zone to tertiary zone (Table 12). The experimental station mean yields varied from $3770 \mathrm{~kg} \mathrm{ha}^{-1}$ to $3250 \mathrm{~kg} \mathrm{ha}^{-1}$, the highest being in the primary zone and decreasing towards tertiary production zone. Mean experimental yields being greater than simulated rainfed yields, reflect the possibility of life saving irrigations given to the experimental trials. On-farm mean yields represented by FLD trials remained at around $1800 \mathrm{~kg} \mathrm{ha}^{-1}$ throughout the three production zones. Yield gap I, taken as the difference of simulated mean and on-farm mean yield, increased from $1400 \mathrm{~kg} \mathrm{ha}^{-1}$ in the primary zone to $1570 \mathrm{~kg} \mathrm{ha}^{-1}$ in the tertiary zone. Another indicator of yield gap I taken as the difference between experimental station yield and on-farm yield, decreased from $1960 \mathrm{~kg} \mathrm{ha}^{-1}$ in the primary zone to $1410 \mathrm{~kg} \mathrm{ha}^{-1}$ in the tertiary zone. Difference between onfarm and district means termed as yield gap II, was 730,1020 and $990 \mathrm{~kg} \mathrm{ha}^{-1}$ in primary to tertiary zones. The total yield gap, which is the sum of these two yield gaps, increased, respectively from 2130 $\mathrm{kg} \mathrm{ha}{ }^{-1}$ in the primary zone to $2560 \mathrm{~kg} \mathrm{ha}^{-1}$ in the tertiary zone.

Table 12. Yield gap of kharif sorghum in different production zones of India.

|  | Primary | Secondary | Tertiary |
| :--- | ---: | ---: | ---: |
|  | $\left(\mathrm{kg} \mathrm{ha}^{-1}\right)$ |  |  |
| Rainfed yields |  |  |  |
| Simulated mean | 3210 | 3390 | 3410 |
| Experimental station mean | 3770 | 3440 | 3250 |
| On-farm mean* | 1810 | 1880 | 1840 |
| District mean* | 1080 | 860 | 850 |
| Yield gaps |  |  |  |
| Simulated - on-farm (YG I) | 1400 | 1510 | 1570 |
| Experimental station - on-farm (YG I) | 1960 | 1560 | 1410 |
| On-farm - District mean (YG II) | 730 | 1020 | 990 |
| Total gap (simulated-District mean) | 2130 | 2530 | 2560 |
| * Based on limited FLD data (Table 9) |  |  |  |
| \# Mean of all districts for each kharif sorghum production zone (Table 6). |  |  |  |

Yield gap of agroecological zones: Simulated and on-farm mean yields were not available for AEZ 2. The experiment station mean yield for this zone was $3580 \mathrm{~kg} \mathrm{ha}^{-1}$; and the gap between experimental station yields and district means was $3360 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 13). AEZ 2 being an arid zone, the variability in crop season rainfalls is often very high both spatially and temporally. As there were a few experimental station yields available, the mean yield presented here may not be a true indicator of the potential productivity for the entire AEZ 2. The gap between simulated rainfed mean and on-farm yield was $1260 \mathrm{~kg} \mathrm{ha}^{-1}$ for AEZ 6 and $1480 \mathrm{~kg} \mathrm{ha}^{-1}$ for AEZ 5. Similarly, the yield gap between experimental station and on-farm means ranged from $1200 \mathrm{~kg} \mathrm{ha}^{-1}$ in AEZ 4 to $2060 \mathrm{~kg} \mathrm{ha}^{-1}$ in AEZ 7. Gap between on-farm mean yield and the district mean yield was low in AEZ 6 and 7 ( 710 to 340 kg ha ${ }^{-1}$ ). The yield gap was the largest at $1120 \mathrm{~kg} \mathrm{ha}^{-1}$ in AEZ 5. Total yield gap across AEZs ranged from 2270 to $3360 \mathrm{~kg} \mathrm{ha}^{-1}$.

Table 13. Yield gap of kharif sorghum in different AEZs of India.

|  | AEZs |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

| Experimental station-on-farm (YG I) | - | 1200 | 1590 | 1590 | 2060 | - |
| On-farm-district (YG II) | - | 1070 | 1120 | 710 | 340 | - |
| Total yield gap | 3360 | 2270 | 2710 | 2300 | 2400 | 2660 |

Yield gap of major states: The gap between simulated rainfed mean yield and on-farm yield ranged from $1040 \mathrm{~kg} \mathrm{ha}^{-1}$ in Karnataka to $1490 \mathrm{~kg} \mathrm{ha}^{-1}$ in Maharashtra and Madhya Pradesh, respectively (Table 14). The yield gap between experimental station mean yield and on-farm mean yield ranged from $1170 \mathrm{~kg} \mathrm{ha}^{-1}$ in Madhya Pradesh to $2300 \mathrm{~kg} \mathrm{ha}^{-1}$ in Andhra Pradesh. The gap between on-farm and district mean yield was the lowest in Andhra Pradesh at $220 \mathrm{~kg} \mathrm{ha}^{-1}$, followed by $450 \mathrm{~kg} \mathrm{ha}^{-1}$ in Maharashtra. In Gujarat, Karnataka, Madhya Pradesh and Rajasthan, these yield gaps ranged from 970 to $1320 \mathrm{~kg} \mathrm{ha}^{-1}$. Total yield gap ranged from $1340 \mathrm{~kg} \mathrm{ha}^{-1}$ in Uttar Pradesh to $3280 \mathrm{~kg} \mathrm{ha}^{-1}$ in Karnataka. The magnitudes of yield gap I and II for different states indicate the extent of technology transfer that has happened from research station to demonstration sites and from demonstration sites to average farmer's fields in a state.

### 4.8 Water Balance Components of Kharif Sorghum

Rainfall: Rainfall is the major source of water supply for crop production in semi-arid regions. Mean rainfall in the primary zone was 660 mm (Tables 15 \& 17). Variability across years was high in some locations like Parbhani, Dharwad and Rajgarh. Because of this, the yields in these locations also had a high variability across years. Mean rainfall in the secondary zone was higher at 770 mm . Jodhpur, Kota, Shajapur and Guna showed a very high variability in rainfall across the years and the CV ranged from 35 to $55 \%$ for these locations. This was reflected in the yield variability across years at these locations. Mean rainfall in the tertiary zone was 670 mm . Sholapur and Rahuri had a lower mean rainfall of less than 400 mm in this zone. These locations also had a high degree of variability across years.

Evapotranspiration: Crop growth and yield are strongly correlated with evapotranspiration (ET) in water-limited environments. Mean ET in the primary zone was 340 mm during the crop growth (Tables 15 \& 17). Akola had a higher ET than the mean. Mean ET in the secondary zone was 350 mm . Variability across years in this zone was higher than the primary zone. The lowest ET of 210 mm was estimated for Jodhpur where the mean rainfall was also lower with a high degree of variability. Mean ET for the tertiary zone was 340 mm . The lowest ET estimated was in Rahuri, which also had lower rainfall with high CV.

Runoff: Mean runoff in the primary zone was 110 mm . But there was a lot of variation across the locations in the amount of runoff (Tables 16 \& 17). Amravati, Dharwad and Jalgaon had about 70 mm of runoff during the crop growth period, which was lower than the mean value. Akola, Parbhani and Rajgarh had mean runoff of more than 200 mm , indicating that there is a great potential to harness this runoff through water harvesting measures for supplemental irrigation to the crop. Secondary zone had a mean runoff of 220 mm . Jodhpur had the lowest runoff potential, which was about 50 mm in this zone. Tertiary zone had a mean runoff of 200 mm . Sholapur and Rahuri had a low runoff, which was 50 mm . Even though the mean runoff in all the zones was more, several locations across the zones had very little runoff. These locations also had a lower rainfall with a high degree of variability across years. Barring these locations, there is a good scope for water harvesting at other locations which can increase the efficiency of crop performance.

Deep Drainage: Primary zone had a mean of 210 mm deep drainage (Tables $16 \& 17$ ). Deep drainage is the fraction of rainfall that enters the soil and goes below the root zone after saturating the soil profile. However, this fraction is not useful to the crop in the field. It has a major contribution in recharging the groundwater table during the season. Secondary zone had a mean deep drainage of 190 mm . Jodhpur and Aurangabad in the zone had a very low component of deep drainage. Tertiary zone had a mean of 140 mm during the crop season. Rahuri, Sholapur and Pune in this zone recorded a very low deep drainage.

Extractable soil water: Extractable soil water is the water available to the crop in the root zone, which is still left at the end of the crop season. This gives a good idea about the water availability for the subsequent crop. Mean extractable water content in the primary zone was 220 mm , followed by secondary zone ( 140 mm ) and tertiary zone ( 110 mm ). Sholapur, Guna, Pune and Aurangabad had very low extractable water contents, indicating that though the seasonal rainfall was low, the crop extracted a larger extent of the water to survive.

### 4.9 Constraints and Opportunities to Kharif Sorghum Production

Across all the regions, shoot fly is an important insect pest. Stem borer is identified as an important constraint in Rajasthan, Haryana, Uttar Pradesh and Uttaranchal. Head bug is another constraint in Tamil Nadu, Andhra Pradesh and Maharashtra. Among the diseases, grain mold is the most important in Tamil Nadu, Karnataka, Andhra Pradesh and Gujarat. The second most important disease in sorghum is identified as ergot in Maharashtra, Andhra Pradesh and Gujarat. All other diseases like downy mildew and rust are not major yield reducers. However, anthracnose can be an important constraint in fodder sorghum.

Among the abiotic stresses, mid-season drought is identified as the most important constraint to sorghum production across the states in India. Drought is common in Maharashtra, Rajasthan, Karnataka, Andhra Pradesh, Tamil Nadu and Uttar Pradesh. Appropriate water conservation and management practices including in-situ water conservation and on-farm water harvesting to utilize rainfall runoff will improve the rainfed yields.
Lack of remunerative market price is a major economic constraint. Farmer's preference for the pearly white grain and roundness of the grain are the major grain quality constraints for adoption of the improved varieties and hybrids. These grain qualities are preferred by consumers and often dictate market prices for the produce. Adoption of improved varieties, integrated nutrient management and IPM practices need to be adopted in the context of integrated watershed management to enhance productivity of kharif sorghum.

### 4.10 Summary

Currently, the total area under kharif sorghum in India is 4.56 M ha with a total production of 4.40 M t and an average productivity of $970 \mathrm{~kg} \mathrm{ha}^{-1}$. Maharashtra, Madhya Pradesh and Karnataka are the major states producing kharif sorghum. Based on the share of sorghum area to the total cropped area in a district, the districts were grouped into production zones for kharif sorghum. The top districts covering $50 \%$ of the cropped area were grouped into primary zone; the next group of districts covering $35 \%$ of area ( 50 to $85 \%$ ) were categorized into secondary zone; and the remaining districts having more than 1000 ha under the cropped area were categorized into the tertiary zone. Similarly, the production and productivity was also studied in different states and AEZs.
Primary production zone had the highest productivity of $1080 \mathrm{~kg} \mathrm{ha}^{-1}$. Secondary and tertiary zones had a mean productivity of 860 and $850 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. In the primary zone, the mean simulated yield across locations ranged from 2510 to $3670 \mathrm{~kg} \mathrm{ha}^{-1}$ with a mean of $3210 \mathrm{~kg} \mathrm{ha}^{-1}$. For the secondary
zone, the range in simulated yield was 1590 to $4430 \mathrm{~kg} \mathrm{ha}^{-1}$ with an overall mean of $3390 \mathrm{~kg} \mathrm{ha}^{-1}$; and for the tertiary zone it ranged from 2520 to $4380 \mathrm{~kg} \mathrm{ha}^{-1}$ with a mean of $3410 \mathrm{~kg} \mathrm{ha}^{-1}$. The total yield gap was divided into yield gap I and yield gap II. The yield gap I or the gap between simulated means and the on-farm means was 1400,1510 and $1570 \mathrm{~kg} \mathrm{ha}^{-1}$ for the primary, secondary and tertiary zones, respectively. The yield gap II or the gap between on-farm mean yield and the district mean yield was 730,1020 and $990 \mathrm{~kg} \mathrm{ha}^{-1}$. The gap between simulated long-term mean yield and the mean district level farmers' yield is termed as total yield gap. The total yield gap for all the production zones was $2410 \mathrm{~kg} \mathrm{ha}^{-1}$. Primary production zone had the lowest gap of $2130 \mathrm{~kg} \mathrm{ha}^{-1}$, followed by secondary production zone with a gap of $2530 \mathrm{~kg} \mathrm{ha}^{-1}$ and tertiary zone with a gap of $2560 \mathrm{~kg} \mathrm{ha}^{-1}$. The lowest long-term mean gap in the primary production was mainly due to the low and erratic rainfall.

Mean seasonal rainfall was 660 mm for the primary zone, 770 mm for the secondary zone and 670 mm for the tertiary zone. Simulated mean runoff for the primary production zone was 110 mm , followed by 220 mm for the secondary zone and 200 mm for the tertiary zone. The fraction of runoff to the seasonal rainfall was higher in the secondary and tertiary zones. Mean simulated deep drainage in the primary production zone was 210 mm , followed by 190 mm for the secondary production zone and 140 mm for the tertiary production zone. Mean deep drainage was 32,25 and 21 per cent of the rainfall for the primary, secondary and tertiary zones, respectively.

For kharif sorghum, among the abiotic stresses, mid-season drought was identified as the most important constraint across the states in India. Across all the regions, shoot fly was an important pest. Stem borer was an important constraint in Rajasthan, Haryana, Uttar Pradesh and Uttaranchal. Head bug was another constraint in Tamil Nadu, Andhra Pradesh and Maharashtra. Grain mold disease affected the growth of the crop in Tamil Nadu, Karnataka, Andhra Pradesh and Gujarat. Ergot also caused a decline in production in Maharashtra, Andhra Pradesh and Gujarat. Lack of remunerative market price is a major economic constraint.

To enhance the productivity of kharif sorghum, integrated watershed-based approach that will involve harvesting of excess rainfall for supplemental irrigation, growing high yielding crop cultivars with desirable quality traits, integrated nutrient management and integrated pest and disease management are needed. Value addition of sorghum products and its multiple uses such as for bio-energy can make it more remunerative for the farmers.

### 5.0 Yield Gap Analysis of Rabi Sorghum

### 5.1 Abstract

Rabi sorghum has better economic value for farmers as compared to kharif sorghum because of its better grain quality for food as well as source of fodder for animals during lean summer period, prior to the onset of rainy season. The present study estimated the production potential and yield gap of rabi sorghum to assess the scope for enhancing its production in various production zones.

CERES-sorghum model available in DSSAT v3.5 was used to simulate sorghum growth and yield to quantify the potential productivity of rabi sorghum for the selected locations. These estimates along with experiment station yield, frontline demonstration (FLD) yield and district level yield data were used to estimate the yield gaps at various technological levels. Simulated rainfed potential, FLD and district mean yields of rabi sorghum were 1310,1480 and $480 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively, for the primary
zone. For the secondary zone, the yields in the same order were 1360,1290 and $680 \mathrm{~kg} \mathrm{ha}^{-1}$. For the tertiary zone, simulated rainfed potential and district mean yields were 1000 and $750 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Total yield gaps for the primary, secondary and tertiary zones was 830,680 and 280 kg $\mathrm{ha}^{-1}$, respectively, indicating the need to scale up the available rabi sorghum production technologies to farmers in the region to abridge the existing yield gaps.

Terminal drought is the major yield constraint for rabi sorghum. Integrated watershed management approach, encompassing harvesting and storing of excess water during the rainy season for supplemental irrigation, high yielding drought resistant cultivars, integrated nutrient and pest management practices are needed to enhance the productivity of rabi sorghum.

### 5.2 Introduction

Rabi sorghum is the important source of food for people and fodder for livestock in the rainfed regions of India. Maharashtra, Karnataka and Andhra Pradesh are the major rabi sorghum producing states occupying about $90 \%$ of the rabi sorghum area. Since 1971, the area under rabi sorghum has decreased, while the productivity has substantially increased. Most of the decline in area has occurred in Andhra Pradesh and Karnataka, where rabi sorghum has been replaced by high value cereals, pulses and oilseeds. There is no decline in area in Maharashtra, which has the lowest average yield. This is due to the high demand for rabi sorghum for grain and fodder during lean months.

Unfavorable soil physical conditions preventing advanced sowing and low water holding capacity of shallow black soils leading to terminal drought to the crop are the main reasons for the lack of increase in productivity in a sustainable manner. Therefore, the input components including supplemental irrigation, rather than the high yielding varieties of rabi sorghum, were responsible for increase in productivity. Currently, rabi sorghum is grown on 5.11 M ha area with a productivity of $590 \mathrm{~kg} \mathrm{ha}^{-1}$ (Database: 2000-02). In view of increasing human and animal population in India, it is important to increase production and productivity to meet the future food and fodder needs. The present study estimated the productivity potential, yield gap and water balance of rabi sorghum in order to assess the scope for enhancing its production.

### 5.3 Production Zones and Soil Resources of Rabi Sorghum

The primary zone of production covers 2.58 M ha in just six districts. This is about 50 per cent of the total rabi sorghum area in India. Out of these six districts, four are in Maharashtra and the rest in Karnataka (Fig. 6 \& Table 19). The secondary zone of production comprises of 12 districts and has 35 per cent ( 1.75 M ha) of the total area sown under rabi sorghum in India. The secondary zone of production falls in parts of Maharashtra, Karnataka and Andhra Pradesh. The tertiary zone comprises 55 districts in India, covering remaining $15 \%(0.77 \mathrm{M} \mathrm{ha)} \mathrm{of} \mathrm{the} \mathrm{total} \mathrm{area} \mathrm{under} \mathrm{rabi} \mathrm{sorghum}$. Tertiary zone is spread out in parts of Maharashtra, Karnataka, Andhra Pradesh, Tamil Nadu, Gujarat and Madhya Pradesh. These areas are characterized by low annual rainfall from 200 mm to 500 mm . Besides, rabi sorghum is a postrainy season crop, purely depending on residual soil moisture and very little occasional rainfall during the crop growth period.

Figure 6. Major production zones of rabi sorghum in India.

Entisols (excluding Orthents) occupy about 60 per cent of the primary production zone of postrainy season sorghum (Fig. 7 \& Table 18). Next to these soils, Vertisols occupy about 37 per cent area. These soils usually have high contents of montmorillonite or illite type of clays. These soils exhibit deep vertical cracks depending on the amount and type of expanding minerals in the profile. Timely operation of tillage becomes crucial in these soils. However, because of the type and amount of clay contents, these profiles usually have high AWHC resulting in high residual moisture storage capacities. This is a useful trait for the postrainy season crops. The secondary zone is dominated by Vertisols occupying 57 per cent of the area followed by Entisols (Orthents) occupying 38 per cent. Tertiary zone is dominated by Alfisols occupying 41 per cent of the area. Vertisols occupy 31 per cent of the area followed by Entisols.

Figure 7. Soil resources in different production zones of rabi sorghum in India.

### 5.4 Rabi Sorghum Productivity in Production Zones, AEZs and States of India

Rabi sorghum productivity in production zones: Primary zone has a total production of 1.23 M t with an average productivity of $480 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 19). The secondary zone has a total production of 1.19 M t with a productivity level of $680 \mathrm{~kg} \mathrm{ha}^{-1}$. The tertiary zone has 0.55 M ha under the crop with the highest productivity of $720 \mathrm{~kg} \mathrm{ha}^{-1}$, but the coefficient of variation for yield is very high ( $60 \%$ ). Total area under rabi sorghum in India is 5.11 M ha with a total production and productivity of 2.99 M t and $590 \mathrm{~kg} \mathrm{ha}{ }^{-1}$, respectively. Increase in productivity from primary to secondary zone may be attributed to the better moisture availability as one moves away from the core area.

Table 19. Area ( M ha), production ( M t ) and productivity ( $\mathrm{kg} \mathrm{ha}^{-1}$ ) of different production zones of rabi sorghum in India (Database: 2000-02).

| Production zone | No. of <br> districts | Area | Production | Productivity | CV* <br> $(\%)$ |
| :--- | :---: | :---: | :---: | :---: | :---: |
| Primary | 6 | 2.58 | 1.24 | 480 | 34 |

| Total | 105 | 5.11 | 2.99 | 590 | 70 |

${ }^{*}$ Coefficient of variation among districts.
Rabi sorghum productivity in agroecological zones: AEZ 6, which is termed as semi-arid dry, has about 4.1 M ha under rabi sorghum, spread in 31 districts of Maharashtra and Karnataka (Fig. 8 \& Table 20). The primary districts are Sholapur, Ahmednagar and Pune in Maharashtra and Gulbarga in Karnataka. Eighty per cent of rabi sorghum growing area and $73 \%$ of total production is from AEZ 6. Average productivity of this zone is about $540 \mathrm{~kg} \mathrm{ha}^{-1}$. AEZ 6 is followed by AEZ 3 ( 0.58 M ha), AEZ $7(0.24 \mathrm{M} \mathrm{ha})$ and AEZ $8(0.07 \mathrm{M} \mathrm{ha})$ in terms of area under rabi sorghum. AEZ 3, termed as arid zone, has about 0.58 M ha under rabi sorghum, primarily in Bijapur district of Karnataka. It has about $11 \%$ of the total area under the crop and contributes about $14 \%$ to the total production of rabi sorghum. It has an average productivity of $700 \mathrm{~kg} \mathrm{ha}^{-1}$. AEZ 7, which is a semi-arid zone, has $5 \%$ of the total area and contributes about $8 \%$ to the total rabi sorghum production. Kurnool district of Andhra Pradesh comes in this AEZ. It has an average productivity of $970 \mathrm{~kg} \mathrm{ha}^{-1}$. AEZ 12 is a sub-humid moist zone and encompasses Chandrapur district of Maharashtra and has the lowest productivity of 360 kg $\mathrm{ha}^{-1}$. Other AEZs have negligible area under the crop, thus contributing little to total rabi sorghum production in the country.

Rabi sorghum productivity in different states of India: Maharashtra, Karnataka and Andhra Pradesh are the three major states growing rabi sorghum in India (Table 21). Madhya Pradesh, Tamil Nadu and Gujarat have negligible area under the crops. Recent years have seen a further reduction in the total rabi sorghum area. Maharashtra is the largest state growing rabi sorghum on 3.21 M ha out of the total of 5.11 M ha of rabi sorghum in India. It is grown in 28 districts and Maharashtra produces about 1.63 M t of sorghum. The average productivity is the lowest among the states at $510 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of 43 per cent. Karnataka is the second largest rabi sorghum growing state with 1.45 M ha under this crop. It produces 0.94 M t of sorghum with a mean productivity of $650 \mathrm{~kg} \mathrm{ha}{ }^{-1}$. Variability of productivity across the districts is very high with 44 per cent coefficient of variation.

Table 20. Area ( M ha), production ( M t ) and productivity ( $\mathrm{kg} \mathrm{ha}^{-1}$ ) in different agroecological zones of rabi sorghum in India (Database: 2000-02).

### 5.5 Rainfed Yield Potential of Rabi Sorghum

Experimental station yields and yield gaps: In the primary zone, Gulbarga had the highest yield (2360 $\mathrm{kg} \mathrm{ha}^{-1}$ ) and Sholapur the least ( $1230 \mathrm{~kg} \mathrm{ha}^{-1}$ ) experimental station yield, with an overall mean yield of $1990 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 22). The mean yields of FLDs in this zone were $1480 \mathrm{~kg} \mathrm{ha}^{-1}$ and the corresponding mean district yields were $530 \mathrm{~kg} \mathrm{ha}^{-1}$. Yield gap I for this zone was $530 \mathrm{~kg} \mathrm{ha}^{-1}$. The yield gap II was about $1010 \mathrm{~kg} \mathrm{ha}^{-1}$. Total mean yield gap for this zone was about $1460 \mathrm{~kg} \mathrm{ha}^{-1}$. In the secondary zone, Karad, Dharwad and Nandyal had high rabi sorghum yields ( 2560 to $2710 \mathrm{~kg} \mathrm{ha}^{-1}$ ). Whereas, Parbhani had the lowest yield ( $1570 \mathrm{~kg} \mathrm{ha}^{-1}$ ). The mean yield of the experimental stations in the secondary zone was $2270 \mathrm{~kg} \mathrm{ha}^{-1}$. FLD yield for this zone was available only for Parbhani ( $1290 \mathrm{~kg} \mathrm{ha}^{-1}$ ). Mean district yields for the zone was $750 \mathrm{~kg} \mathrm{ha}^{-1}$. Yield gap I for the secondary zone was only $280 \mathrm{~kg} \mathrm{ha}^{-1}$. Yield gap II for the zone was $630 \mathrm{~kg} \mathrm{ha}^{-1}$. These yield gaps are rather poor estimates because of scanty data on FLD yields. Total yield gap for the secondary zone was $1520 \mathrm{~kg} \mathrm{ha}^{-1}$. There were only two locations in the tertiary zone. Mean experimental station yields for the tertiary zone was $2940 \mathrm{~kg} \mathrm{ha}^{-1}$. Data on FLDs were not available for this zone. Considering the mean district yields of $700 \mathrm{~kg} \mathrm{ha}^{-1}$, the total yield gap for the tertiary zone was $2230 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 22).

In general, the yield gaps for rabi sorghum were much less than those estimated for kharif sorghum across locations. This is because the experimental station yields of rabi sorghum were less than those of kharif sorghum as the postrainy sorghum is solely grown on residual soil moisture with little rainfall during the season.

### 5.6 Simulated Potential Rainfed Yields

Potential yield of locations: In the primary zone, Sholapur with Barsi soil series had the maximum simulated potential productivity ( $1850 \mathrm{~kg} \mathrm{ha}^{-1}$ ) and the lowest was on Umbraj soil series ( $1010 \mathrm{~kg} \mathrm{ha}^{-1}$ ) (Table 23). The CV in yield ranged from 46 to $58 \%$ across locations. The mean maximum and minimum yields were 3070 and $270 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. Secondary zone had a mean yield of 1360 kg ha ${ }^{-1}$. The highest mean yield of 2150 kg ha ${ }^{-1}$ was recorded at Belgaum with Huguluru series and the lowest of $930 \mathrm{~kg} \mathrm{ha}^{-1}$ at Parbhani with Jambha series. CV varied from 23\% at Belgaum with Huguluru series to $56 \%$ at Aurangabad. Mean yield of tertiary zone was $1000 \mathrm{~kg} \mathrm{ha}^{-1}$. Maximum mean yield of $2050 \mathrm{~kg} \mathrm{ha}^{-1}$ was at Wardha; whereas the lowest mean yield of $450 \mathrm{~kg} \mathrm{ha}^{-1}$ was at Jalgaon with Linga series. CV in the tertiary zone ranged from $31 \%$ at Wardha to $62 \%$ at Jalgaon with Linga series.

| Mean |  | 2270 | 1290 | 750 | 280 | 630 | 1520 |
| Tertiary Zone |  |  |  |  |  |  |  |
| Hagari | Karnataka | 2620 | - | 800 | - | - | 1820 |
| Madhira | Andhra Pradesh | 3260 | - | 610 | - | - | 2640 |
| Mean |  | 2940 | - | 710 | - | - | 2230 |

Potential yield of production zones: The long-term simulated mean rainfed yield in the primary zone was $1310 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of $28 \%$ (Table 24). Mean yield in the secondary zone was $1360 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of $31 \%$. Tertiary zone had a mean yield of $1000 \mathrm{~kg} \mathrm{ha}^{-1}$ with a high CV of $58 \%$ across locations. Though there was not much of a difference in the mean yields across zones, the secondary zone had the highest grain yield. Despite low yield levels, farmers prefer to grow this crop on marginal lands mainly for fodder as there is usually no alternative crop in the absence of irrigation.

Potential yields of major states: Maharashtra and Karnataka account for 4.65 M ha of rabi sorghum. Mean rainfed yield of several locations in Maharashtra was $1110 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 24). Such low yields of rabi sorghum were due to its major dependency on soil-profile stored moisture. Mean rainfall was only 90 mm during the crop growth period. Variability in the yields across locations was high with a CV of 37 per cent. This was due to a high variability in the rainfall (CV 65 per cent) across locations coupled with poor soils. Mean yield in Karnataka was slightly higher at $1640 \mathrm{~kg} \mathrm{ha}^{-1}$ with a coefficient of variation of 30 per cent across locations in this state. Mean rainfall during the crop season in Karnataka was also the same as in Maharashtra (Table 22).

Simulated rainfed potential yields of agroecological zones: Majority of the locations in Maharashtra and Karnataka come under AEZ 6. This zone had a simulated mean yield of $1170 \mathrm{~kg} \mathrm{ha}^{-1}$ for rabi sorghum (Table 24). Variability in yield across locations was very high with a CV of 37 per cent. Lower mean yields were because the crop is mainly grown on residual soil moisture. Mean crop season rainfall was only 90 mm with a high CV of $59 \%$ across locations. AEZ 10 had data from only one station. The yield in this location was $2050 \mathrm{~kg} \mathrm{ha}^{-1}$ with a crop season rainfall of 100 mm .

### 5.7 Yield Gaps

Yield gaps of production zones: Mean simulated yields were 1310, 1360 and $1000 \mathrm{~kg} \mathrm{ha}^{-1}$ from primary to tertiary zones (Table 25). The corresponding experimental station yields were 1990, 2270 and $2940 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. On-farm yields were 1480 and $1290 \mathrm{~kg} \mathrm{ha}^{-1}$ for the primary and secondary zone, respectively. We did not have any on-farm yield data for the tertiary zone. District mean yields for the three production zones were very low at 480,680 and $720 \mathrm{~kg} \mathrm{ha}{ }^{-1}$. Yield gap I taken as the difference between experimental station and on-farm mean yield was 510 and $980 \mathrm{~kg} \mathrm{ha}^{-1}$ for the primary and secondary zone, respectively. As the on-farm yield was more than simulated mean yield, the yield gap I for the primary zone was taken as zero. Yield gap I for the secondary zone was also negligible ( $70 \mathrm{~kg} \mathrm{ha}^{-1}$ ). As rabi sorghum is mainly grown on the residual soil moisture with negligible rainfall during the crop growth period, the simulated rainfed long-term averages were a mere reflection of this. Higher mean experimental station and some FLD yields indicated the possibility of life saving irrigations given in these trials. Total yield gap taken as the difference between the simulated mean yield and district mean yield was 830,680 and $280 \mathrm{~kg} \mathrm{ha}^{-1}$ for primary, secondary and tertiary zones, respectively. In general, the rabi sorghum yield levels were much lower than the kharif sorghum yields and the coefficient of variation (CV) was very high indicating high yield instability across years.

Table 25. Yield gap of rabi sorghum in different production zones of India.

|  | Primary | Secondary | Tertiary |

| Simulated - on-farm (YG I) | 510 | 980 | - |
| Experimental station - on-farm (YG I) | 1000 | 610 | - |
| On-farm - district mean (YG II) | 830 | 680 | 280 |
| Total gap (simulated-district mean) |  |  |  |

[^3]Yield gap of agroecological zones: Major rabi sorghum producing AEZs are 3 and 6. In AEZ 6, simulated rainfed yields were lower than the on-farm yields. This could be because the simulated rainfed yields shown here are long-term mean of yield simulations of several locations; whereas the on-farm data was available only for less than three years. The yield gap between experimental station and on-farm yield was the lowest at $690 \mathrm{~kg} \mathrm{ha}^{-1}$ in AEZ 6 (Table 26). On-farm to district level yield gaps was $850 \mathrm{~kg} \mathrm{ha}^{-1}$. These yield gaps were in fact more than the district means for these AEZs. This gap may not be possible to abridge easily in practice because the district level data is an average of the whole district yield and reflects the effect of the spatial variability in rainfall and soil moisture storage capacities and other soil properties. But the on-farm trial yields were the result of very few locations and often reflect the best possible situations in terms of natural resources in that region. Through appropriate soil, crop and nutrient management practices a part of this yield gap can be reduced at least for locations where the biophysical conditions in terms of rainfall and soils are favorable.

Experimental station to on-farm and on-farm to district yield gaps in AEZ 3 were around $800 \mathrm{~kg} \mathrm{ha}^{-1}$. In AEZ 7, experimental station to on-farm yield gaps were high at $1400 \mathrm{~kg} \mathrm{ha}^{-1}$; whereas on-farm to district yield gaps were $590 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 26).

* Based on experiment station data in the absence of simulated yields

Yield gap of major states: Simulated rainfed yields were lower than the on-farm yields in Maharashtra (Table 27). This is because rainfed simulations were carried out for a longer time period, often for 15 to 26 years for each location, than the number of years for which the actual crop yield data were available. The data of on-farm yields were available from very few locations and often for two or three years only. Thus, the simulations captured the effects of temporal and spatial variations in rainfall on crop yields. On-farm to district level yield gap in Maharashtra was about $880 \mathrm{~kg} \mathrm{ha}^{-1}$, indicating that yield gap could be narrowed through improved crop and nutrient management. For Karnataka, the gap between simulated and on-farm yield was just $80 \mathrm{~kg} \mathrm{ha}^{-1}$. The gap between on-farm and district mean yield was about $910 \mathrm{~kg} \mathrm{ha}^{-1}$, again indicating the potential to increase rabi sorghum yields by scaling up of the improved technologies from on-farm demonstrations to the average farmers' situation.

Table 27. Yield gap of rabi sorghum in major states of India.

### 5.8 Water Balance Components of Rabi Sorghum

Rainfall: The rainfall during crop growth period in all the production zones was low and highly variable, which caused high variability in the crop yields across years. Mean rainfall was 180 mm for the primary zone, 90 mm for the secondary zone and 70 mm for the tertiary zone (Tables $28 \& 30$ ). Coefficient of variation in rainfall across various production zones ranged from 43 to $94 \%$. Low rainfall and its high spatial and temporal variability were the main constraints for the rabi sorghum crop to perform optimally. Water harvesting in the rainy season and supplemental irrigation during the postrainy season can enhance rabi sorghum yields in these areas.

Evapotranspiration: Evapotranspiration (ET) by the crop during the season had a direct bearing on the biomass and grain yield of the crop. Mean seasonal ET was 200 mm for the primary zone, 160 mm for the secondary zone and 130 mm for the tertiary zone (Tables $28 \& 30$ ).

| Amravati | Maharashtra | Jambha | 18 | 70 | 70 | 0 | 180 | 120 | 44 | 40 | 240 |

Runoff: The amount of runoff is determind by the amount and intensity of rainfall besides soil physical attributes. As the rainfall during the crop growth period was less, the absolute mounts of runoff can be expected to be very little. Mean runoff in the primary zone was only 20 mm with some chance of significant runoff in some years (Tables $29 \& 30$ ). Mean runoff in the secondary zone was also 20 mm with a high variability across years indicating greater potential to harvest runoff in some years compared to the primary zone. Mean runoff in the tertiary zone was still low at 10 mm .

Deep Drainage: Mean value of deep drainage in the primary zone was about 70 mm , with a high variability. Both secondary and tertiary zones had 10 mm of deep drainage each with high variability across years (Tables $29 \& 30$ ). Very little deep drainage across production zones was again because of the low input of rainfall during the crop growth period.

Extractable soil water: Extractable soil water is the water available for plant growth at the end of the crop growth period. Mean extractable soil water in the primary zone was 40 mm in the entire soil profile with a high degree of variability. This shows that most of available water in the profile had been utilized by the crop and the crop performance was limited by the water availability. Mean available water in the secondary zone was 100 mm with the lowest of 10 mm at Aurangabad and Parbhani. Mean available water in the tertiary zone was also 100 mm . Jambha soil series, both in Akola and Jalgaon regions, had the highest extractable soil water at the end of the season. The variability across locations in this zone was also very high.

### 5.9 Constraints and Opportunities to Rabi Sorghum Production

Major abiotic constraint for rabi sorghum production is terminal drought as the crop is mainly dependent on stored soil moisture. Shoot fly, head bugs and stalk rots are constraints in southern Andhra Pradesh and southern Karnataka. In Gujarat, north Karnataka and southern Maharashtra, shoot fly and stalk rot are common. Shallow soils are common constraint, leading to low levels of stored moisture. Variability of rainfall across years in the rainy season resulted in periodic deficits in the stored moisture.

### 5.10 Summary

Currently, total area under rabi sorghum is 5.11 M ha with a total production of 2.99 Mt and an average productivity of $590 \mathrm{~kg} \mathrm{ha}^{-1}$. Primary production zone had the lowest productivity of 480 kg $\mathrm{ha}^{-1}$. Secondary and tertiary zones had a mean productivity of 680 and $720 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively. The district level farmers mean yield of the three production zones for rabi sorghum was $630 \mathrm{~kg} \mathrm{ha}^{-1}$. Mean FLD yield of primary and secondary production zones was $1380 \mathrm{~kg} \mathrm{ha}^{-1}$. Long-term simulated rainfed mean yield of all the production zones was $1220 \mathrm{~kg} \mathrm{ha}^{-1}$. Mean simulated yields were high in the primary and secondary zones ( $1310-1360 \mathrm{~kg} \mathrm{ha}^{-1}$ ) and decreased towards the tertiary zone ( 1000 $\mathrm{kg} \mathrm{ha}{ }^{-1}$ ). Total yield gap (simulated mean rainfed yield minus farmers mean yield) for all the production zones was $590 \mathrm{~kg} \mathrm{ha}^{-1}$. Primary production zone had the highest gap of $830 \mathrm{~kg} \mathrm{ha}^{-1}$, followed by secondary production zone with a gap of $680 \mathrm{~kg} \mathrm{ha}^{-1}$ and tertiary zone with a gap of 280 $\mathrm{kg} \mathrm{ha}{ }^{-1}$. Yield gaps I and II for the production could not be estimated accurately because of insufficient FLD data. Wherever FLD data were available, the FLD yields were more than the simulated yields. This may be due to the supplemental irrigation to the rabi crop given by some farmers in the zone.

| Runoff (mm) | 20 | 0-70 | 20 | 0-140 | 10 | 0-80 |
| Deep drainage (mm) | 70 | 0-260 | 10 | 0-170 | 10 | 0-120 |
| Evapotranspiration (mm) | 200 | 70-340 | 160 | 30-320 | 130 | 20-290 |

High yielding drought-resistant rabi sorghum varieties and hybrids of good grain quality are required to increase rabi sorghum production. Integrated watershed management approach, encompassing storing of excess water harvested during the rainy period to provide for supplemental irrigation to the rabi crop, growing of high yielding drought-resistant cultivars and integrated nutrient and pest management practices are needed to enhance the productivity of the crop.

### 6.0 Production Trends of Millet in the World and India

### 6.1 Pearl Millet Production in the World

India, Niger, Nigeria, Sudan, Mali, Burkina Faso and Senegal are the major countries producing pearl millet in the world. Total area under pearl millet production is 28 M ha with total production of 21.8 Mt . As the FAO database does not report pearl millet data separately from the data of other types of millets grown in the world, these data may include a very small fraction of other minor millets grown in these countries. Initially the area under pearl millet declined from about 30 M ha in 1970 to about 25 M ha in 1987, but later it recovered to almost to original levels (Fig. 9). However, total production continued to increase from 17 Mt in 1970 to 24 Mt in 2005. In the same period, the pearl millet productivity increased from 590 to $800 \mathrm{~kg} \mathrm{ha}^{-1}$, thus significantly contributing to the total production.

Figure 9. Global trends in area, production and productivity of pearl millet.

Table 31. Area, production and productivity of pearl millet in different countries during 2003-05.

| Country | Area <br> $(\mathrm{M} \mathrm{ha})$ | Per cent of <br> total area | Production <br> $(\mathrm{M} \mathrm{t})$ | Productivity <br> $\left(\mathrm{kg} \mathrm{ha}{ }^{-1}\right)$ |
| :--- | :---: | :---: | :---: | :---: |
| India | 9.81 | 35 | 9.30 | 940 |
| Niger | 7.92 | 28 | 2.48 | 310 |

| Sudan | 2.03 | 7 | 0.60 | 300 |
| Mali | 1.61 | 6 | 1.13 | 700 |
| Burkina Faso | 1.27 | 5 | 1.11 | 870 |
| Senegal | 0.78 | 3 | 0.52 | 670 |
| Total | 28.03 |  | 21.85 | 780 |

Source: FAOSTAT, 2007; For India data: Ministry of Agriculture, Govt. of India, 2006.

Out of 28.0 M ha of area in the world, India has the largest area (about 35 per cent) under pearl millet cultivation. India and Nigeria put together have about 63 per cent of the global area under millets (Table 31). Among the seven countries, Nigeria has the highest productivity ( 1450 kg ha ${ }^{-1}$ ), followed by India ( $940 \mathrm{~kg} \mathrm{ha}{ }^{-1}$ ), Burkina Faso ( $870 \mathrm{~kg} \mathrm{ha}{ }^{-1}$ ), Mali ( $700 \mathrm{~kg} \mathrm{ha}{ }^{-1}$ ) and Senegal ( $670 \mathrm{~kg} \mathrm{ha}{ }^{-1}$ ). Sudan and Niger have the lowest productivity ( 300 to $310 \mathrm{~kg} \mathrm{ha}^{-1}$ ). All these major countries grow millets in predominantly rainfed systems on marginal soils. Rainfall regimes are very low and practically no chemical fertilizers are applied.

### 6.2 Pearl Millet Production in India

Although, there are year-to-year variations in area sown to pearl millet, total area under pearl millet has decreased from about 13 M ha in 1970 to about 9.6 M ha in the year 2005 (Fig. 10). Variability in total production across the years is large. It varied from 12.1 Mt to about 4 Mt . Major reason for the variability in the production and productivity is the high variability of rainfall. Drought is the main factor for the lack of yield stability.

Rajasthan is the largest producer with about 42.1 per cent of total cultivated area of pearl millet in India. It contributes about 45.5 per cent of total pearl millet production in the country (2001-03 statistics). Gujarat, Maharashtra, Uttar Pradesh and Haryana together contribute about 39.5 per cent of total area and 46.4 per cent of total production. Productivity of pearl millet in the country has increased since 1970s. Mean productivity during the 1970-75 period was $450 \mathrm{~kg} \mathrm{ha}^{-1}$, which increased to $860 \mathrm{~kg} \mathrm{ha}^{-1}$ during 2000-05. This indicates $90 \%$ increase in productivity over the 36 years.

### 7.0 Yield Gap Analysis of Pearl Millet

### 7.1 Abstract

In India, pearl millet is grown on the most marginal and least fertile soils in the arid and semi-arid regions. Using crop simulation approach and review of existing crop yield data of research station experiments, frontline demonstrations and farmers' current yields, the potential yields and yield gaps of pearl millet were assessed for increasing productivity to meet the future food and fodder needs.

Figure 10. Area, production and productivity of pearl millet in India (Source: Ministry of Agriculture, Govt. of India, 2006).

Based on concentration of the crop in each district, the pearl millet growing area was classified into primary, secondary and tertiary zones. The primary production zone had the lowest productivity of 580 $\mathrm{kg} \mathrm{ha}{ }^{-1}$, followed by secondary ( $1020 \mathrm{~kg} \mathrm{ha}^{-1}$ ) and tertiary ( $1030 \mathrm{~kg} \mathrm{ha}^{-1}$ ) zone. The overall district level mean yield of farmers across the three production zones was $770 \mathrm{~kg} \mathrm{ha}^{-1}$. Mean simulated rainfed potential yield was the lowest at $1430 \mathrm{~kg} \mathrm{ha}^{-1}$ for the primary production zone, $1960 \mathrm{~kg} \mathrm{ha}^{-1}$ for the secondary and $2090 \mathrm{~kg} \mathrm{ha}^{-1}$ for the tertiary zone. Long-term simulated rainfed mean yield of the three production zones was $1830 \mathrm{~kg} \mathrm{ha}^{-1}$. Front line demonstrations (FLDs) with improved technology in farmers' fields characterize the rainfed achievable yields. Mean FLD yield across the production zones was $1870 \mathrm{~kg} \mathrm{ha}^{-1}$, which is similar to the simulated rainfed mean yield. The gap between long-term simulated rainfed mean yield and the district level farmers mean yield across all the production zones was $950 \mathrm{~kg} \mathrm{ha}^{-1}$. Primary production zone had the lowest yield gap of $880 \mathrm{~kg} \mathrm{ha}^{-1}$, followed by the secondary zone with $940 \mathrm{~kg} \mathrm{ha}^{-1}$; and the tertiary zone with $1060 \mathrm{~kg} \mathrm{ha}^{-1}$. These yield gaps indicate the need to scale up the available pearl millet production technologies. Mean simulated water surplus (runoff plus deep drainage) was 140 mm for the primary, 180 mm for the secondary and 270 mm for the tertiary zones.

The above analysis shows that pearl millet productivity can be increased 1.8 to 2.3 times the current levels of productivity. This is possible by growing improved cultivars with improved soil fertility and crop management practices and efficient use of rainfall.

### 7.2 Introduction

Pearl millet (Pennisetum glaucum (L.) R.Br) is the most drought tolerant warm-season cereal crop grown as staple food grain and source of feed and fodder on about 30 M ha in the arid and semi-arid tropical regions of Asia and Africa. Along with barley, it is specifically adapted to grow on the most marginal, driest and the least fertile cereal growing environments (Bidinger et al. 2004). Pearl millet is largely grown on light textured soils in the annual rainfall regime of $400-750 \mathrm{~mm}$, where sorghum and maize often fail to produce any yield (Harinarayana et al. 1999). Pearl millet is the most important cereal crop in India, both in terms of area ( 9.4 M ha ) and production ( 8.5 M t ), with an average productivity of $900 \mathrm{~kg} \mathrm{ha}^{-1}$ (Database: 2001-03). India is also the largest producer of pearl millet in the world in terms of area and production. In spite of increase in production and productivity of pearl millet in India over the years, its productivity is still much below the potential levels that can be achieved with improved management and high yielding cultivars.

This study was aimed at quantifying productivity potential and yield gap of pearl millet. Spatial and temporal variations in yield gap at various technological levels (i.e., yield gaps between simulated rainfed potential yields, experimental station rainfed yields, frontline demonstration yields and actual farmers' yields) have been presented to assess the scope for enhancing pearl millet production in India. Constraints that limit pearl millet production and the opportunities available to enhance its productivity are also discussed.

### 7.3 Production Zones and Soil Resources of Pearl Millet

Pearl millet is grown in 327 districts in India with a total area of 9.4 M ha. The primary zone has 4.8 M ha spread out in 14 districts. Out of these 14 districts, 9 districts are in Rajasthan (Table 33). The secondary zone has 3.2 M ha covered by pearl millet. A total of 36 districts come under this zone. Pearl millet area in tertiary zone is distributed in 124 districts. The remaining 153 districts fall in the "others" category with pearl millet cultivation.

Most of the primary production zone is in Rajasthan and with some parts in Gujarat and Maharashtra. Secondary and tertiary zones are rather spread out in other states (Fig. 11). Entisols occupy major portion (about 59\%) of the primary zone and most of these are Psamments. These soils are generally loamy fine sands to coarse textured soils. These soils are not saturated for long periods during crop growth periods. Large tracts of these soils are shifting or established sand dunes primarily in Rajasthan. The suborder Orthents forms about $22 \%$ area in this zone. These are usually very fine sands or fine textured soils. After Entisols, Aridisols form a major fraction (about 31\% of area) of soils in the primary zone. These soils are mostly found in dry desert areas predominantly in Rajasthan and Gujarat and they are very low in organic matter content. The soil profile of this soil order remains moist for a very short period of the year. The suborder Orthids, which are characterized by the absence of argillic horizon and without sodic horizons are common in this zone. Vertisols and Inceptisols comprise about four per cent each in the primary zone. Secondary zone also is dominated with Entisols with 39.8 per cent area. Aridisols are next with 23.2 per cent area. But unlike the primary zone, this zone has 18.7 per cent of area with more productive Vertisols and 15.2 per cent under Inceptisols. The tertiary zone is dominated by Alfisols ( 28.3 per cent), followed by Entisols occupying about $26.6 \%$ of the area, Vertisols 24.9 per cent and 15.1 per cent under Inceptisols (Table 32).

Figure 12. Soil resources in different production zones of pearl millet in India.

### 7.4 Pearl Millet Productivity in Production Zones, AEZs and States of India

Pearl millet productivity of production zones: The primary zone has 4.8 M ha spread out in 14 districts. Out of these 14 districts, 9 districts are in Rajasthan. Average productivity is $750 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of 36 per cent (Table 33). The secondary zone has 3.2 M ha covered by pearl millet and 36 districts come under this zone. The average productivity is $1060 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of 38 per cent. Pearl millet area in the tertiary zone is distributed in 124 districts having an average productivity of $1050 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of 41 per cent indicating high variability in productivity among districts in this zone. With diverse agroclimatic conditions in the districts classified as "others" the average pearl millet yield is $950 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of 50 per cent. Increase in yield of pearl millet from primary to tertiary zone could be attributed to the better moisture regime as one moves away from the primary zone.

Table 33. Area, production and productivity of different production zones of pearl millet in India (Database: 2001-03).

| Production <br> zones | No. of <br> districts | Area <br> $(\mathrm{M} \mathrm{ha})$ | Production <br> $(\mathrm{M} \mathrm{t)}$ | Productivity <br> $\left(\mathrm{kg} \mathrm{ha}^{-1}\right)$ | $\mathrm{CV}^{*}$ <br> $(\%)$ |

* Coefficient of variation among districts.

Area, production and productivity in the agroecological zones: Pearl millet is grown in 13 agroecological zones from arid ecosystem (AEZ 2) to sub-humid ecosystem (AEZ 14) with progressive increase in moisture availability. However, the major area and production is in AEZs 2, 4 and 6 (Fig. 13 \& Table 34). AEZ 2 comprises of Western Plain, parts of Rajasthan and Gujarat, which is hot and arid ecoregion with desert and saline soils. The length of the growing period (LGP) is 60-90 days. An area of about 4.52 M ha is under pearl millet cultivation in AEZ 2. The mean productivity of this zone is $730 \mathrm{~kg} \mathrm{ha}^{-1}$. Variability of productivity across districts in this zone is very high with a CV of 40 per cent. Because of the extent of area under pearl millet, this zone is the most important zone for pearl millet production in India. AEZ 4 is the second largest with 2.47 M ha under the crop and average productivity of $1280 \mathrm{~kg} \mathrm{ha}^{-1}$. AEZ 4 comprises of Northern Plains and Central Highlands that have hot arid climate, light alluvium derived soils and LGP of 90 to 150 days. Pearl millet in AEZ 4 is spread in parts of Rajasthan, Uttar Pradesh, Haryana, Punjab, Madhya Pradesh and Gujarat. AEZ 6 has the third largest area under pearl millet encompassing Deccan Plateau with shallow and medium deep black soils. This is the hot semi-arid zone with a LGP of 90-150 days. Pearl millet in this AEZ is cultivated mostly in Maharashtra and parts of Karnataka and in Nizamabad district in Andhra Pradesh. Total area under pearl millet is 1.58 M ha with an average productivity of $660 \mathrm{~kg} \mathrm{ha}^{-1}$. Pearl millet is grown up to AEZ 19. However, the major concentration of the crop is confined to the arid and semi-arid regions (AEZs 2-9) only.

Pearl millet productivity in different states of India: Rajasthan is the major state with an area of 4.74 M ha under pearl millet production (Table 35). Out of the total 8.49 Mt produced in the country, 3.74 Mt is produced in Rajasthan. Average productivity in the state is one of the lowest at $790 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of $34 \%$. High variability in productivity is due to the fact that most of the area is in the arid zones with low seasonal rainfall. Maharashtra is the second largest state with 1.42 M ha under the crop with a mean productivity of $670 \mathrm{~kg} \mathrm{ha}^{-1}$. Gujarat follows with an area of 1.08 M ha and a mean productivity of $1280 \mathrm{~kg} \mathrm{ha}^{-1}$. Variability in productivity across districts in Gujarat is high with a CV of 29 per cent. Productivity of pearl millet in Tamil Nadu is high ( $1070 \mathrm{~kg} \mathrm{ha}^{-1}$ ) but the area under pearl millet is negligible at 0.13 M ha.

Figure 13. Agroecological zones of pearl millet in India.

### 7.5 Rainfed Yield Potential of Pearl Millet

Experimental station yields and yield gaps: Experimental station mean yield of the primary zone was $1700 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 36). The only district of Jaipur in the primary zone had a mean FLD yield of 1810 $\mathrm{kg} \mathrm{ha}{ }^{-1}$. The higher FLD yield than the experimental yield could be attributed to spatial variability in soil or rainfall. The corresponding district mean yield was $610 \mathrm{~kg} \mathrm{ha}^{-1}$. As the FLD mean yield of Jaipur was higher than the experimental yield, the yield gap was taken as nil. Because of insufficient number of FLD sites in the primary zone, we could not have a good estimate of the yield gaps I and II. However, the total yield gap for the zone was $1090 \mathrm{~kg} \mathrm{ha}^{-1}$.

Mean experimental station yield for the secondary production zone was $2070 \mathrm{~kg} \mathrm{ha}^{-1}$. There was a lot of variation in the FLD mean yields of corresponding districts. It ranged from 940 kg to $2520 \mathrm{~kg} \mathrm{ha}{ }^{-1}$ with a mean of $1600 \mathrm{~kg} \mathrm{ha}^{-1}$. The variation among district yields was also high, which averaged to $930 \mathrm{~kg} \mathrm{ha}^{-1}$. Mean total yield gap calculated for this zone was $1140 \mathrm{~kg} \mathrm{ha}^{-1}$. Because of the lack of FLD data for some locations in the secondary zone, the estimates of mean yield gap I and II were approximate, which were 610 and $790 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively.

Experimental station mean yield of the tertiary zone was $2440 \mathrm{~kg} \mathrm{ha}^{-1}$. There were only two corresponding districts having FLD data. Mean FLD yield for this zone was $2190 \mathrm{~kg} \mathrm{ha}^{-1}$. Jamnagar in Gujarat showed a higher FLD mean yield than the experimental station mean yield. Because of insufficient FLD data, it was difficult to have a reasonable estimates of yield gap I and yield gap II for this zone. Total yield gap for this zone was $1590 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 36). Total yield gap as observed for the three production zones indicated the potential to increase the farmers yield through transfer of technology from research stations to the farmers field and its subsequent scaling up for larger areas.

### 7.6 Simulated Potential Rainfed Yields

Potential yield of locations: The simulated rainfed mean yield of the primary production zone was $1430 \mathrm{~kg} \mathrm{ha}^{-1}$. Long-term simulations under rainfed situation showed that the CV in yield for all the three locations of Jodhpur, Jaipur and Rahuri exceeded 40 per cent. This clearly demonstrates that because of large variability in yields of pearl millet across years, farmers have to face a high degree of risk in pearl millet production in this zone. Mean yield in the secondary zone was $1960 \mathrm{~kg} \mathrm{ha}^{-1}$. Except Pune in Maharashtra, all other locations had shown a CV greater than 40 per cent in pearl millet yields. The tertiary zone was fairly well spread across India. Mean long-term yield across the locations in this zone was $2090 \mathrm{~kg} \mathrm{ha}^{-1}$. The mean yield increased from primary to tertiary zones. There was a large variation in CV of yields across the locations in the tertiary zone. Belgaum and Dharwad showed a lower CV indicating a relatively stable yield across years in Karnataka. All other locations had a high degree of variation across years (Table 37).
Potential yields of production zones: Primary production zone had the lowest mean yield of 1430 kg $\mathrm{ha}^{-1}$ (Table 38). This production zone had the highest area under pearl millet. Yield variability across locations was also evident from the high coefficient of variation, which was greater than 30 per cent. Seasonal rainfall in this zone was the lowest at a mean of 320 mm . The secondary zone had a higher mean yield of $1960 \mathrm{~kg} \mathrm{ha}^{-1}$ with a CV of 48 per cent across locations. The increase in the mean yield could be explained by a higher mean crop season rainfall of 430 mm . The highest mean yield of 2090 $\mathrm{kg} \mathrm{ha}{ }^{-1}$ was observed in the tertiary zone. Similarly, this zone had the highest mean crop season rainfall of 520 mm .

Potential yields of major states: Rajasthan is the major state growing pearl millet. Mean simulated rainfed yield in this state was $1460 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 38). Variability across locations was very high as evidenced by a high coefficient of variation of 32 per cent. The lower yields were due to low mean crop season rainfall of 420 mm . Madhya Pradesh had the highest mean yields by $2530 \mathrm{~kg} \mathrm{ha}{ }^{-1}$. Mean crop season rainfall at locations in Madhya Pradesh was also higher at 700 mm . Karnataka had a mean yield of $2170 \mathrm{~kg} \mathrm{ha}^{-1}$. Even though, the yields were better than Rajasthan, variability across locations was very high with a CV of 50 per cent. This was due to a high degree of variability ( $C V=41 \%$ ) of crop season rainfall. Maharashtra had a mean yield of $2000 \mathrm{~kg} \mathrm{ha}^{-1}$. Variability across locations was high with a CV of 33 per cent.
Potential yields of agroecological zones: The highest mean yield of $2470 \mathrm{~kg} \mathrm{ha}^{-1}$ was simulated for AEZ 10 (Table 38). This zone had good crop season rainfall of 700 mm . However, pearl millet was grown in a very limited area in this zone. Major pearl millet area falls in AEZ 2 and 3. These zones had low mean yields of 950 and $710 \mathrm{~kg} \mathrm{ha}^{-1}$. This was because of low crop season rainfall of 300 and 230 mm in these zones. A major portion of the pearl millet area was concentrated in these unfavorable zones with low rainfall, poor soils and a high degree of variability of rainfall across the years.
Table 37. Seasonal rainfall and simulated grain yield of pearl millet at different locations across India.

### 7.7 Yield Gaps

Yield gap of production zones: Because of progressive increase in mean rainfall from primary to tertiary production zone, the simulated mean yields, experimental station mean yields, FLD yields and district average yields increased from primary to the tertiary zone (Table 39). Experimental station yields in all production zones were somewhat higher than the mean simulated yields but remained below the simulated maximum possible yields. This was because simulations were carried out for many years, whereas the experimental data was available only for ten years. Yield gap I across production zones ranged from nil to $470 \mathrm{~kg} \mathrm{ha}^{-1}$ with mean of $200 \mathrm{~kg} \mathrm{ha}^{-1}$. Yield gap II was higher than the yield gap I, which ranged from 540 to $1140 \mathrm{~kg} \mathrm{ha}^{-1}$ with a mean of $920 \mathrm{~kg} \mathrm{ha}^{-1}$ for the production zones. Yield gap II formed a larger part of the total yield gap (yield gap between the experimental and district mean yield), indicating greater scope for adopting the already available technologies by farmers for productivity enhancement. Yield gap between the simulated potential and mean district yield increased from 680 kg ha ${ }^{-1}$ for the primary zone to $1040 \mathrm{~kg} \mathrm{ha}^{-1}$ for the tertiary zone with a mean of $880 \mathrm{~kg} \mathrm{ha}^{-1}$. The data indicates that the productivity of pearl millet could be increased 1.8 to 2.3 times from the current level of productivity in the three production zones.

Table 39. Yield gap of pearl millet in production zones.

|  | Primary | Secondary |  | Tertiary |
| :--- | ---: | ---: | ---: | ---: |
|  | $\left(\mathrm{kg} \mathrm{ha}^{-1}\right)$ |  |  |  |

| Simulated mean - district mean |  |  |  |  |

* Taken from Table 33

Yield gap of agroecological zones: As the experiment station mean yields for the agroecological zones were generally higher than the simulated mean yields, the total yield gaps estimated based on the experiment station yields were wider than those estimated with simulated mean yields. These yield gaps in general increased from AEZ 2 to AEZ 8. AEZ 2 had the lowest yield gap of $1020 \mathrm{~kg} \mathrm{ha}^{-1}$ and AEZ 8 had the maximum yield gap of $2490 \mathrm{~kg} \mathrm{ha}^{-1}$ (Table 40). This is because of increase in rainfall amount and decrease in its variability as one moves from AEZ 2 to AEZ 8. Based on the simulated yields, the total yield gap ranged from 220 to $1440 \mathrm{~kg} \mathrm{ha}^{-1}$ for the AEZs. In most cases, the yield gap II was larger than the yield gap I, indicating greater need to transfer existing pearl millet production technologies from demonstration sites to the farmers' fields.

Table 40. Yield gap of pearl millet in different AEZs of India.

[^5]Yield gap of major states: Simulated yields for Andhra Pradesh, Gujarat, Haryana and Tamil Nadu were not available because of the lack of input data for executing the pearl millet model. Similarly, total yield gap based on the experiment station data was wider in Andhra Pradesh, Karnataka, Madhya Pradesh, Maharashtra and Tamil Nadu as compared to other states (Table 41). Such comparison between states for total yield gap based on simulated yields was not possible because of lack of simulated data for some states. Except for Madhya Pradesh and Maharashtra, yield gap II was larger than yield gap I. For Gujarat, Haryana and Rajasthan, the FLD yields were higher than the experiment station yields, indicating that on-farm trials at some sites in these states might have been conducted under more favorable environments or provided with supplemental irrigation. Nevertheless, larger total yield gaps indicate the scope of enhanced productivity of pearl millet by proper crop and nutrient management practices.

* Taken from Table 35

### 7.8 Water Balance Components of Pearl Millet

Rainfall: Mean seasonal rainfall across locations and years was 320 mm in the primary zone, 420 mm in the secondary zone and 520 mm in the tertiary zone. All the three locations in the primary zone had a very high CV of rainfall with Jodhpur being the highest (61\%) (Tables 42 \& 44). High variability in rainfall was the main reason for unstable yields across years. Secondary zone had about 25 per cent more rainfall than the primary zone. A clear reflection of this could be seen in the increase of mean yield of this zone. However, all the other locations except Jalgaon exhibited a high CV in rainfall. The tertiary zone had almost 100 mm more rainfall than the secondary zone. Although, the mean yields of this zone were higher than those in the secondary zone, the quantum of increase in yields did not match with the increase of rainfall. The reason could be the high CV, indicating a high degree of variability across years or poor crop management. Dharwad was an exception, with a CV less than 30 per cent.

Runoff: Runoff is determined by soil hydraulic properties, amount and more importantly the intensity of rainfall. Mean simulated runoff in the primary zone was 50 mm during the cropping season, which is rather low. Mean runoff in the secondary zone was 90 mm . Tertiary zone had a mean runoff of 120 mm during the crop season (Tables 42 \& 44). Although, there was a large variation among locations within a production zone to produce surface runoff, tertiary zone had the highest runoff potential for water harvesting and its use as supplemental irrigation to increase crop yields.

Deep drainage: A fraction of the rainfall during the crop season, which enters the soil profile is lost through deep drainage. However, this helps increasing the groundwater levels through recharge. Deep drainage was more than runoff for all the production zones. Simulated runoff was 90 mm for the primary zone, 100 mm for the secondary zone and 150 mm for the tertiary zone, respectively (Tables $42 \& 44$ ).

Evapotranspiration: Evapotranspiration (ET) is a combined term representing soil evaporation and plant transpiration during the crop growth period. Primary zone had mean ET of 200 mm , which ranged from 120 to 270 mm across locations (Tables $43 \& 44$ ). Simulated mean ET for the secondary zone was 250 mm , which was $20 \%$ more than that simulated for the primary zone. Simulated ET for the tertiary zone was the same as for the secondary zone.

Extractable water: Extractable water left in the soil profile at the end of the season gives an indication for the potential to grow second crop or to extend the crop growth period of the current crop for greater yield potential at a given site or production zone. Amount of water left in the soil profile on an average was 110 mm for the primary zone, 140 mm for the secondary zone and 170 mm for the tertiary zone, respectively, indicating increase in production (Table 43).

Table 44. Water balance components of pearl millet during the season in different production zones of India.

| Water balance components | Primary zone |  | Secondary zone |  | Tertiary zone |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  | Mean | Range | Mean | Range | Mean | Range |
| Rainfall (mm) | 320 | 80-680 | 420 | 180-700 | 520 | 250-910 |
| Runoff (mm) | 50 | 0-260 | 90 | 20-230 | 120 | 20-330 |
| Deep drainage (mm) | 90 | 0-260 | 100 | 0-220 | 150 | 20-330 |
| Evapotranspiration (mm) | 200 | 120-270 | 250 | 170-330 | 250 | 170-340 |

### 7.9 Constraints and Opportunities to Pearl Millet Production

Major pearl millet growing area is in the arid region of India (Rajasthan and Northern Gujarat) where rainfall is low and erratic. Therefore, drought is the most common constraint. Low inherent soil fertility and low nutrient input due to high rainfall variability is another constraint. Among the biotic constraints, downy mildew is the most destructive disease causing severe economic losses. Other minor diseases affecting pearl millet are smut, ergot and rust (ICRISAT 2002). Improved millet hybrids resistant to downy mildew and drought-tolerant have increasingly become available, which need to be adopted for increasing productivity. In some areas, significant amount of water is lost and surface runoff and deep drainage, which needs to be harvested and used as supplemental irrigation. In other dry areas, $i n$-situ moisture conservation practices need to be adopted. Integrated nutrient management practices are required to enhance the pearl millet productivity and increase the water use efficiency. Many of these technologies are available on the shelve and need to be refined and adopted for different agroecologies of pearl millet.

### 7.10 Summary

Pearl millet production is an essential component of rainfed agriculture in the arid and semi-arid regions of India. In this report, we determined the potential yields and yield gaps of pearl millet to estimate future food production possibilities. Pearl millet growing area was classified into primary, secondary and tertiary zones based on the concentration of the crop in each district. Primary production zone has about 4.8 M ha concentrated in just 14 districts. Majority of this area is in Rajasthan, Gujarat and Maharashtra. These areas are characterized by low annual rainfall and marginal soils and a high degree of variation in productivity within the production zones. Primary production zone had the lowest productivity of $750 \mathrm{~kg} \mathrm{ha}^{-1}$ followed by secondary ( $1060 \mathrm{~kg} \mathrm{ha}^{-1}$ ) and tertiary ( $1050 \mathrm{~kg} \mathrm{ha}^{-1}$ ) zone. Mean yield of farmers in the production zones was only $950 \mathrm{~kg} \mathrm{ha}{ }^{-1}$. To assess the potential yields and yield gaps, the districts from each production zone were taken up, where the required input data for crop simulation were available. Mean simulated potential yields was the lowest at $1430 \mathrm{~kg} \mathrm{ha}^{-1}$ in the primary production zone. Secondary and tertiary zones had a mean simulated yield of 1960 and $2090 \mathrm{~kg} \mathrm{ha}^{-1}$, respectively.

Long-term simulated rainfed mean yield of all the production zones was $1830 \mathrm{~kg} \mathrm{ha}^{-1}$. The gap between long-term simulated rainfed mean yields and the mean district level farmers yields from all the production zones was $880 \mathrm{~kg} \mathrm{ha}^{-1}$. Primary production zone had the lowest gap of $680 \mathrm{~kg} \mathrm{ha}^{-1}$, followed by secondary production zone with a gap of $900 \mathrm{~kg} \mathrm{ha}^{-1}$ and tertiary zone with a gap of $1040 \mathrm{~kg} \mathrm{ha}^{-1}$. Mean FLD yields of all the production zones was $1870 \mathrm{~kg} \mathrm{ha}^{-1}$. The mean yield gap between FLD and the district level farmers yields among all the production zones was $920 \mathrm{~kg} \mathrm{ha}^{-1}$.

All the water balance components like rainfall, runoff and deep drainage were the lowest in the primary zone and progressively increased from primary to tertiary production zones. Mean seasonal rainfall in the primary zone was the lowest at 320 mm , followed by 420 mm in the secondary zone and 520 mm in the tertiary zone. Simulated long-term mean runoff in the primary production zone was 50 mm , followed by 90 mm in the secondary zone and 120 mm in the tertiary zone. Mean simulated long-term deep drainage in the primary production zone was 90 mm followed by 100 mm in the secondary production zone and 150 mm in the tertiary production zone. These results show that the growing environment of the primary production zone, which has about 50 per cent of the total area under pearl millet concentrated in just 14 districts, has least favorable natural resources to support pearl millet production.

Drought is the major constraint across all the production zones of pearl millet. Low and erratic rainfall is the major cause for the water stress faced by the crop. Due to the risk factor of crop failures, farmers resort to low to no nutrient inputs. However, this study has shown a significant scope for increasing crop yields of pearl millet in all the three production zones of India.

About ICRISAT ${ }^{\text {® }}$
The International Crops Research Institute for the Semi-Arid Tropics (ICRISAT) is a nonprofit, non-political organization that does innovative agricultural research and capacity building for sustainable development with a wide array of partners across the globe. ICRISAT's mission is to help empower 600 million poor people to overcome hunger, poverty and a degraded environment in the dry tropics through better agriculture. ICRISAT belongs to the Alliance of Centers of the Consultative Group on International Agricultural Research (CGIAR).
